Title Nonparametric Kernel Smoothing Methods for Mixed Data Types

Maintainer Jeffrey S. Racine <racinej@mcmaster.ca>

Description Nonparametric (and semiparametric) kernel methods that seamlessly handle a mix of continuous, unordered, and ordered factor data types. We would like to gratefully acknowledge support from the Natural Sciences and Engineering Research Council of Canada (NSERC:www.nserc.ca), the Social Sciences and Humanities Research Council of Canada (SSHRC:www.sshrc.ca), and the Shared Hierarchical Academic Research Computing Network (SHARCNET:www.sharcnet.ca).

b.star

*Compute Optimal Block Length for Stationary and Circular Bootstrap***Description**

b.star is a function which computes the optimal block length for the continuous variable data using the method described in Patton, Politis and White (2009).

Usage

```
b.star(data,  
       Kn = NULL,  
       mmax= NULL,  
       Bmax = NULL,  
       c = NULL,  
       round = FALSE)
```

Arguments

data	data, an $n \times k$ matrix, each column being a data series.
Kn	See footnote c, page 59, Politis and White (2004). Defaults to $\text{ceiling}(\log_{10}(n))$.
mmax	See Politis and White (2004). Defaults to $\text{ceiling}(\sqrt{n})+Kn$.
Bmax	See Politis and White (2004). Defaults to $\text{ceiling}(\min(3*\sqrt{n}, n/3))$.
c	See Politis and White (2004). Defaults to $qnorm(0.975)$.
round	whether to round the result or not. Defaults to FALSE.

Details

b.star is a function which computes optimal block lengths for the stationary and circular bootstraps. This allows the use of tsboot from the `boot` package to be fully automatic by using the output from b.star as an input to the argument `l =` in tsboot. See below for an example.

Value

A $k \times 2$ matrix of optimal bootstrap block lengths computed from data for the stationary bootstrap and circular bootstrap (column 1 is for the stationary bootstrap, column 2 the circular).

Examples

```
set.seed(12345)

# Function to generate an AR(1) series

ar.series <- function(phi,epsilon) {
  n <- length(epsilon)
  series <- numeric(n)
  series[1] <- epsilon[1]/(1-phi)
  for(i in 2:n) {
    series[i] <- phi*series[i-1] + epsilon[i]
  }
  return(series)
}

yt <- ar.series(0.1,rnorm(10000))
b.star(yt,round=TRUE)

yt <- ar.series(0.9,rnorm(10000))
b.star(yt,round=TRUE)
```

cps71

Canadian High School Graduate Earnings

Description

Canadian cross-section wage data consisting of a random sample taken from the 1971 Canadian Census Public Use Tapes for male individuals having common education (grade 13). There are 205 observations in total.

Usage

```
data("cps71")
```

Format

A data frame with 2 columns, and 205 rows.

logwage the first column, of type numeric

age the second column, of type integer

Examples

```
data("cps71")
attach(cps71)

plot(age, logwage, xlab="Age", ylab="log(wage)")

detach(cps71)
```

Engel95

1995 British Family Expenditure Survey

Description

British cross-section data consisting of a random sample taken from the British Family Expenditure Survey for 1995. The households consist of married couples with an employed head-of-household between the ages of 25 and 55 years. There are 1655 household-level observations in total.

Usage

```
data("Engel95")
```

Format

A data frame with 10 columns, and 1655 rows.

food expenditure share on food, of type numeric
catering expenditure share on catering, of type numeric
alcohol expenditure share on alcohol, of type numeric
fuel expenditure share on fuel, of type numeric
motor expenditure share on motor, of type numeric
fares expenditure share on fares, of type numeric
leisure expenditure share on leisure, of type numeric
logexp logarithm of total expenditure, of type numeric
logwages logarithm of total earnings, of type numeric
nkids number of children, of type numeric

gradients

Extract Gradients

Description

gradients is a generic function which extracts gradients from objects.

Usage

```
gradients(x, ...)
```

S3 method for class 'condensity'

```
gradients(x, errors = FALSE, ...)
```

S3 method for class 'condistribution'

```
gradients(x, errors = FALSE, ...)
```

S3 method for class 'npregression'

```
gradients(x, errors = FALSE, ...)
```

S3 method for class 'qregression'

```
gradients(x, errors = FALSE, ...)
```

S3 method for class 'singleindex'

```
gradients(x, errors = FALSE, ...)
```

Arguments

x	an object for which the extraction of gradients is meaningful.
...	other arguments.
errors	a logical value specifying whether or not standard errors of gradients are desired. Defaults to FALSE.

Details

This function provides a generic interface for extraction of gradients from objects.

Value

Gradients extracted from the model object x.

Note

This method currently only supports objects from the `np` library.

     ylab="GDP (millions of Lire, 1990=base)")

detach(Italy)
```

Description

This package provides a variety of nonparametric and semiparametric kernel methods that seamlessly handle a mix of continuous, unordered, and ordered factor data types (unordered and ordered factors are often referred to as ‘nominal’ and ‘ordinal’ categorical variables respectively). A vignette containing many of the examples found in the help files accompanying the **np** package that is intended to serve as a gentle introduction to this package can be accessed via `vignette("np", package="np")`.

For a listing of all routines in the **np** package type: `library(help="np")`.

Bandwidth selection is a key aspect of sound nonparametric and semiparametric kernel estimation. **np** is designed from the ground up to make bandwidth selection the focus of attention. To this end, one typically begins by creating a ‘bandwidth object’ which embodies all aspects of the method, including specific kernel functions, data names, data types, and the like. One then passes these bandwidth objects to other functions, and those functions can grab the specifics from the bandwidth object thereby removing potential inconsistencies and unnecessary repetition. Furthermore, many functions such as `plot` (which automatically calls `npplot`) can work with the bandwidth object directly without having to do the subsequent companion function evaluation.

As of **np** version 0.20-0, we allow the user to combine these steps. When using **np** versions 0.20-0 and higher, if the first step (bandwidth selection) is not performed explicitly then the second step will automatically call the omitted first step bandwidth selector using defaults unless otherwise specified, and the bandwidth object could then be retrieved retroactively if so desired via `objectname$bws`. Furthermore, options for bandwidth selection will be passed directly to the bandwidth selector function. Note that the combined approach would not be a wise choice for certain applications such as when bootstrapping (as it would involve unnecessary computation since the bandwidths would properly be those for the original sample and not the bootstrap resamples) or when conducting quantile regression (as it would involve unnecessary computation when different quantiles are computed from the same conditional cumulative distribution estimate).

There are two ways in which you can interact with functions in **np**, either i) using data frames, or ii) using a formula interface, where appropriate.

To some, it may be natural to use the data frame interface. The R `data.frame` function preserves a variable's type once it has been cast (unlike `cbind`, which we avoid for this reason). If you find this most natural for your project, you first create a data frame casting data according to their type (i.e., one of continuous (default, `numeric`), `factor`, `ordered`). Then you would simply pass this data frame to the appropriate np function, for example `npudensbw(dat=data)`.

To others, however, it may be natural to use the formula interface that is used for the regression examples, among others. For nonparametric regression functions such as `npreg`, you would proceed as you would using `lm` (e.g., `bw <- npregbw(y~factor(x1)+x2)`) except that you would of course not need to specify, e.g., polynomials in variables, interaction terms, or create a number of dummy variables for a factor. Every function in np supports both interfaces, where appropriate.

Note that if your factor is in fact a character string such as, say, X being either "MALE" or "FEMALE", np will handle this directly, i.e., there is no need to map the string values into unique integers such as (0,1). Once the user casts a variable as a particular data type (i.e., `factor`, `ordered`, or continuous (default, `numeric`)), all subsequent methods automatically detect the type and use the appropriate kernel function and method where appropriate.

All estimation methods are fully multivariate, i.e., there are no limitations on the number of variables one can model (or number of observations for that matter). Execution time for most routines is, however, exponentially increasing in the number of observations and increases with the number of variables involved.

Nonparametric methods include unconditional density (distribution), conditional density (distribution), regression, mode, and quantile estimators along with gradients where appropriate, while semiparametric methods include single index, partially linear, and smooth (i.e., varying) coefficient models.

A number of tests are included such as consistent specification tests for parametric regression and quantile regression models along with tests of significance for nonparametric regression.

A variety of bootstrap methods for computing standard errors, nonparametric confidence bounds, and bias-corrected bounds are implemented.

A variety of bandwidth methods are implemented including fixed, nearest-neighbor, and adaptive nearest-neighbor.

A variety of data-driven methods of bandwidth selection are implemented, while the user can specify their own bandwidths should they so choose (either a raw bandwidth or scaling factor).

A flexible plotting utility, `npplot` (which is automatically invoked by `plot`), facilitates graphing of multivariate objects. An example for creating postscript graphs using the `npplot` utility and pulling this into a LaTeX document is provided.

The function `npksum` allows users to create or implement their own kernel estimators or tests should they so desire.

The underlying functions are written in C for computational efficiency. Despite this, due to their nature, data-driven bandwidth selection methods involving multivariate numerical search can be time-consuming, particularly for large datasets. A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

To cite the np package, type `citation("np")` from within R for details.

Details

The kernel methods in np employ the so-called ‘generalized product kernels’ found in Hall, Racine, and Li (2004), Li, Lin, and Racine (2013), Li, Ouyang, and Racine (2013), Li and Racine (2003), Li and Racine (2004), Li and Racine (2007), Li and Racine (2010), Ouyang, Li, and Racine (2006), and Racine and Li (2004), among others. For details on a particular method, kindly refer to the original references listed above.

We briefly describe the particulars of various univariate kernels used to generate the generalized product kernels that underlie the kernel estimators implemented in the np package. In a nutshell, the generalized kernel functions that underlie the kernel estimators in np are formed by taking the product of univariate kernels such as those listed below. When you cast your data as a particular type (continuous, factor, or ordered factor) in a data frame or formula, the routines will automatically recognize the type of variable being modelled and use the appropriate kernel type for each variable in the resulting estimator.

Second Order Gaussian (x is continuous) $k(z) = \exp(-z^2/2)/\sqrt{2\pi}$ where $z = (x_i - x)/h$, and $h > 0$.

Second Order Truncated Gaussian (x is continuous) $k(z) = (\exp(-z^2/2) - \exp(-b^2/2))/(\operatorname{erf}(b/\sqrt{2})\sqrt{2\pi} - 2b \exp(-b^2/2))$ where $z = (x_i - x)/h$, $b > 0$, $|z| \leq b$ and $h > 0$.

See [nptgauss](#) for details on modifying b .

Second Order Epanechnikov (x is continuous) $k(z) = 3(1 - z^2/5)/(4\sqrt{5})$ if $z^2 < 5$, 0 otherwise, where $z = (x_i - x)/h$, and $h > 0$.

Uniform (x is continuous) $k(z) = 1/2$ if $|z| < 1$, 0 otherwise, where $z = (x_i - x)/h$, and $h > 0$.

Aitchison and Aitken (x is a (discrete) factor) $l(x_i, x, \lambda) = 1 - \lambda$ if $x_i = x$, and $\lambda/(c - 1)$ if $x_i \neq x$, where c is the number of (discrete) outcomes assumed by the factor x .

Note that λ must lie between 0 and $(c - 1)/c$.

Wang and van Ryzin (x is a (discrete) ordered factor) $l(x_i, x, \lambda) = 1 - \lambda$ if $|x_i - x| = 0$, and $((1 - \lambda)/2)\lambda^{|x_i - x|}$ if $|x_i - x| \geq 1$.

Note that λ must lie between 0 and 1.

Li and Racine (x is a (discrete) factor) $l(x_i, x, \lambda) = 1$ if $x_i = x$, and λ if $x_i \neq x$.

Note that λ must lie between 0 and 1.

Li and Racine Normalised for Unconditional Objects (x is a (discrete) factor) $l(x_i, x, \lambda) = 1/(1 + (c - 1)\lambda)$ if $x_i = x$, and $\lambda/(1 + (c - 1)\lambda)$ if $x_i \neq x$.

Note that λ must lie between 0 and 1.

Li and Racine (x is a (discrete) ordered factor) $l(x_i, x, \lambda) = 1$ if $|x_i - x| = 0$, and $\lambda^{|x_i - x|}$ if $|x_i - x| \geq 1$.

Note that λ must lie between 0 and 1.

Li and Racine Normalised for Unconditional Objects (x is a (discrete) ordered factor) $l(x_i, x, \lambda) = (1 - \lambda)/(1 + \lambda)$ if $|x_i - x| = 0$, and $(1 - \lambda)/(1 + \lambda)\lambda^{|x_i - x|}$ if $|x_i - x| \geq 1$.

Note that λ must lie between 0 and 1.

So, if you had two variables, x_{i1} and x_{i2} , and x_{i1} was continuous while x_{i2} was, say, binary (0/1), and you created a data frame of the form `X <- data.frame(x1,x2=factor(x2))`, then the kernel function used by np would be $K(\cdot) = k(\cdot) \times l(\cdot)$ where the particular kernel functions $k(\cdot)$ and $l(\cdot)$ would be, say, the second order Gaussian (`ckertype="gaussian"`) and Aitchison

and Aitken (ukertype="aitchisonaitken") kernels by default, respectively (note that for conditional density and distribution objects we can specify kernels for the left-hand side and right-hand side variables in this manner using cykertype="gaussian", cxxkertype="gaussian" and uykertype="aitchisonaitken", uxkertype="aitchisonaitken").

Note that higher order continuous kernels (i.e., fourth, sixth, and eighth order) are derived from the second order kernels given above (see Li and Racine (2007) for details).

For particulars on any given method, kindly see the references listed for the method in question.

 npcdens

Kernel Conditional Density Estimation with Mixed Data Types

Description

npcdens computes kernel conditional density estimates on $p + q$ -variate evaluation data, given a set of training data (both explanatory and dependent) and a bandwidth specification (a conbandwidth object or a bandwidth vector, bandwidth type, and kernel type) using the method of Hall, Racine, and Li (2004). The data may be continuous, discrete (unordered and ordered factors), or some combination thereof.

Usage

```
npcdens(bws, ...)
```

```
## S3 method for class 'formula'
```

```
npcdens(bws, data = NULL, newdata = NULL, ...)
```

```
## S3 method for class 'call'
```

```
npcdens(bws, ...)
```

```
## S3 method for class 'conbandwidth'
```

```
npcdens(bws,
        txdat = stop("invoked without training data 'txdat'"),
        tydat = stop("invoked without training data 'tydat'"),
        exdat,
        eydat,
        gradients = FALSE,
        ...)
```

```
## Default S3 method:
```

```
npcdens(bws, txdat, tydat, ...)
```

Arguments

bws a bandwidth specification. This can be set as a conbandwidth object returned from a previous invocation of `npcdensbw`, or as a $p + q$ -vector of bandwidths, with each element i up to $i = q$ corresponding to the bandwidth for column i in `tydat`, and each element i from $i = q + 1$ to $i = p + q$ corresponding to the bandwidth for column $i - q$ in `txdat`. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, training data, and so on.

gradients	a logical value specifying whether to return estimates of the gradients at the evaluation points. Defaults to FALSE.
...	additional arguments supplied to specify the bandwidth type, kernel types, and so on. This is necessary if you specify <i>bws</i> as a $p+q$ -vector and not a <code>conbandwidth</code> object, and you do not desire the default behaviours. To do this, you may specify any of <code>bwmethod</code> , <code>bwscaling</code> , <code>bwtype</code> , <code>cxkertype</code> , <code>cxkerorder</code> , <code>cykertype</code> , <code>cykerorder</code> , <code>uxkertype</code> , <code>uykertype</code> , <code>oxkertype</code> , <code>oykertype</code> , as described in npcdensbw .
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npcdensbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
txdat	a p -variate data frame of sample realizations of explanatory data (training data). Defaults to the training data used to compute the bandwidth object.
tydat	a q -variate data frame of sample realizations of dependent data (training data). Defaults to the training data used to compute the bandwidth object.
exdat	a p -variate data frame of explanatory data on which conditional densities will be evaluated. By default, evaluation takes place on the data provided by <code>txdat</code> .
eydat	a q -variate data frame of dependent data on which conditional densities will be evaluated. By default, evaluation takes place on the data provided by <code>tydat</code> .

Details

`npcdens` implements a variety of methods for estimating multivariate conditional distributions ($p + q$ -variate) defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2004) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

Training and evaluation input data may be a mix of continuous (default), unordered discrete (to be specified in the data frames using `factor`), and ordered discrete (to be specified in the data frames using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see [np](#) for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

`npcdens` returns a `condensity` object. The generic accessor functions `fitted`, `se`, and `gradients`, extract estimated values, asymptotic standard errors on estimates, and gradients, respectively, from

the returned object. Furthermore, the functions `predict`, `summary` and `plot` support objects of both classes. The returned objects have the following components:

<code>xbw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the explanatory data, <code>txdat</code>
<code>ybw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the dependent data, <code>tydat</code>
<code>xeval</code>	the evaluation points of the explanatory data
<code>yeval</code>	the evaluation points of the dependent data
<code>condens</code>	estimates of the conditional density at the evaluation points
<code>conderr</code>	standard errors of the conditional density estimates
<code>congrad</code>	if invoked with <code>gradients = TRUE</code> , estimates of the gradients at the evaluation points
<code>congerr</code>	if invoked with <code>gradients = TRUE</code> , standard errors of the gradients at the evaluation points
<code>log_likelihood</code>	log likelihood of the conditional density estimate

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

 npcdensbw

Kernel Conditional Density Bandwidth Selection with Mixed Data Types

Description

npcdensbw computes a conbandwidth object for estimating the conditional density of a $p + q$ -variate kernel density estimator defined over mixed continuous and discrete (unordered, ordered) data using either the normal-reference rule-of-thumb, likelihood cross-validation, or least-squares cross validation using the method of Hall, Racine, and Li (2004).

Usage

```
npcdensbw(...)  
  
## S3 method for class 'formula'

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.

xdat	a p -variate data frame of explanatory data on which bandwidth selection will be performed. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
ydat	a q -variate data frame of dependent data on which bandwidth selection will be performed. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
bws	a bandwidth specification. This can be set as a <code>conbandwidth</code> object returned from a previous invocation, or as a $p+q$ -vector of bandwidths, with each element i up to $i = q$ corresponding to the bandwidth for column i in <code>ydat</code> , and each element i from $i = q + 1$ to $i = p + q$ corresponding to the bandwidth for column $i - q$ in <code>xdat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
...	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.
bwmethod	which method to use to select bandwidths. <code>cv.ml</code> specifies likelihood cross-validation, <code>cv.ls</code> specifies least-squares cross-validation, and <code>normal-reference</code> just computes the ‘rule-of-thumb’ bandwidth h_j using the standard formula $h_j = 1.06\sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation}, \text{mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. Note that when there exist factors and the normal-reference rule is used, there is zero smoothing of the factors. Defaults to <code>cv.ml</code> .
bwscaling	a logical value that when set to <code>TRUE</code> the supplied bandwidths are interpreted as ‘scale factors’ (c_j), otherwise when the value is <code>FALSE</code> they are interpreted as ‘raw bandwidths’ (h_j for continuous data types, λ_j for discrete data types). For continuous data types, c_j and h_j are related by the formula $h_j = c_j\sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of continuous variable j defined as $\min(\text{standard deviation}, \text{mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(2P+l)}$, where here j denotes discrete variable j . Defaults to <code>FALSE</code> .
bwtype	character string used for the continuous variable bandwidth type, specifying the type of bandwidth to compute and return in the <code>conbandwidth</code> object. Defaults to <code>fixed</code> . Option summary: <code>fixed</code> : compute fixed bandwidths <code>generalized_nn</code> : compute generalized nearest neighbors <code>adaptive_nn</code> : compute adaptive nearest neighbors
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to <code>FALSE</code> , a <code>conbandwidth</code> object will be returned with bandwidths set to those specified in <code>bws</code> . Defaults to <code>TRUE</code> .
cxkertype	character string used to specify the continuous kernel type for <code>xdat</code> . Can be set as <code>gaussian</code> , <code>epanechnikov</code> , or <code>uniform</code> . Defaults to <code>gaussian</code> .

cxkerorder	numeric value specifying kernel order for xdat (one of (2,4,6,8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
cykertype	character string used to specify the continuous kernel type for ydat. Can be set as gaussian, epanechnikov, or uniform. Defaults to gaussian.
cykerorder	numeric value specifying kernel order for ydat (one of (2,4,6,8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
uxkertype	character string used to specify the unordered categorical kernel type. Can be set as aitchisonaitken or liracine. Defaults to aitchisonaitken.
uykertype	character string used to specify the unordered categorical kernel type. Can be set as aitchisonaitken or liracine.
oxkertype	character string used to specify the ordered categorical kernel type. Can be set as wangvanryzin or liracine. Defaults to liracine.
oykertype	character string used to specify the ordered categorical kernel type. Can be set as wangvanryzin or liracine.
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points
remin	a logical value which when set as TRUE the search routine restarts from located minima for a minor gain in accuracy. Defaults to TRUE.
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
ftol	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01*\sqrt{.Machine\$double.eps}$).
tol	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine's floating point precision). Defaults to $1.490116e-04$ ($1.0e+04*\sqrt{.Machine\$double.eps}$).
small	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\sqrt{\epsilon}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision)). Defaults to $small = 1.490116e-05$ ($1.0e+03*\sqrt{.Machine\$double.eps}$).
lbc.dir, dfc.dir, cfac.dir, initc.dir	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
lbd.dir, hbd.dir, dfac.dir, initd.dir	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details
lbc.init, hbc.init, cfac.init	lower bound, upper bound, and non-random initial values for scale factors for numeric variables for Powell's algorithm. See Details
lbd.init, hbd.init, dfac.init	lower bound, upper bound, and non-random initial values for scale factors for categorical variables for Powell's algorithm. See Details

scale.init.categorical.sample	a logical value that when set to TRUE scales lbd.dir, hbd.dir, dfac.dir, and initd.dir by $n^{-2/(2P+l)}$, n the number of observations, P the order of the kernel, and l the number of numeric variables. See Details
memfac	The algorithm to compute the least-squares objective function uses a block-based algorithm to eliminate or minimize redundant kernel evaluations. Due to memory, hardware and software constraints, a maximum block size must be imposed by the algorithm. This block size is roughly equal to memfac*10 ⁵ elements. Empirical tests on modern hardware find that a memfac of 500 performs well. If you experience out of memory errors, or strange behaviour for large data sets (>100k elements) setting memfac to a lower value may fix the problem.

Details

npcdensbw implements a variety of methods for choosing bandwidths for multivariate distributions ($p + q$ -variate) defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2004) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

The cross-validation methods employ multivariate numerical search algorithms (direction set (Powell’s) methods in multidimensions).

Bandwidths can (and will) differ for each variable which is, of course, desirable.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

npcdensbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the xdat and ydat parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frames xdat and ydat may be a mix of continuous (default), unordered discrete (to be specified in the data frames using `factor`), and ordered discrete (to be specified in the data frames using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form dependent data \sim explanatory data, where dependent data and explanatory data are both series of variables specified by name, separated by the separation character ‘+’. For example, `y1 + y2 ~ x1 + x2` specifies that the bandwidths for the joint distribution of variables y1 and y2 conditioned on x1 and x2 are to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The optimizer invoked for search is Powell’s conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and, when restarting, random

values for successive invocations. Bandwidths for numeric variables are scaled by robust measures of spread, the sample size, and the number of numeric variables where appropriate. Two sets of parameters for bandwidths for numeric can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell’s algorithm does not involve explicit computation of the function’s gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable ‘tuning’ for various methods rather than for the user themselves.

Value

`npcdensbw` returns a `conbandwidth` object, with the following components:

<code>xbw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the explanatory data, <code>xdat</code>
<code>ybw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the dependent data, <code>ydat</code>
<code>fval</code>	objective function value at minimum

if `bwtype` is set to `fixed`, an object containing bandwidths (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables.

The functions `predict`, `summary` and `plot` support objects of type `conbandwidth`.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(xdat,ydat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

 npcdist

Kernel Conditional Distribution Estimation with Mixed Data Types

Description

npcdist computes kernel cumulative conditional distribution estimates on $p + q$ -variate evaluation data, given a set of training data (both explanatory and dependent) and a bandwidth specification (a condbandwidth object or a bandwidth vector, bandwidth type, and kernel type) using the method of Li and Racine (2008) and Li, Lin, and Racine (2013). The data may be continuous, discrete (unordered and ordered factors), or some combination thereof.

Usage

```

npcdist(bws, ...)

## S3 method for class 'formula'
npcdist(bws, data = NULL, newdata = NULL, ...)

## S3 method for class 'call'
npcdist(bws, ...)

## S3 method for class 'condbandwidth'
npcdist(bws,
        txdat = stop("invoked without training data 'txdat'"),
        tydat = stop("invoked without training data 'tydat'"),
        exdat,
        eydat,
        gradients = FALSE,
        ...)

```

```
## Default S3 method:
npcdist(bws, txdat, tydat, ...)
```

Arguments

bws	a bandwidth specification. This can be set as a <code>condbandwidth</code> object returned from a previous invocation of <code>npcdistbw</code> , or as a $p + q$ -vector of bandwidths, with each element i up to $i = q$ corresponding to the bandwidth for column i in <code>tydat</code> , and each element i from $i = q + 1$ to $i = p + q$ corresponding to the bandwidth for column $i - q$ in <code>txdat</code> . If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, training data, and so on.
gradients	a logical value specifying whether to return estimates of the gradients at the evaluation points. Defaults to FALSE.
...	additional arguments supplied to specify the bandwidth type, kernel types, and so on. This is necessary if you specify <code>bws</code> as a $p+q$ -vector and not a <code>condbandwidth</code> object, and you do not desire the default behaviours. To do this, you may specify any of <code>bwmethod</code> , <code>bwscaling</code> , <code>bwtype</code> , <code>cxkertype</code> , <code>cxkerorder</code> , <code>cykertype</code> , <code>cykerorder</code> , <code>uxkertype</code> , <code>oxkertype</code> , <code>oykertype</code> , as described in <code>npcdistbw</code> .
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npcdistbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
txdat	a p -variate data frame of sample realizations of explanatory data (training data). Defaults to the training data used to compute the bandwidth object.
tydat	a q -variate data frame of sample realizations of dependent data (training data). Defaults to the training data used to compute the bandwidth object.
exdat	a p -variate data frame of explanatory data on which cumulative conditional distributions will be evaluated. By default, evaluation takes place on the data provided by <code>txdat</code> .
eydat	a q -variate data frame of dependent data on which cumulative conditional distributions will be evaluated. By default, evaluation takes place on the data provided by <code>tydat</code> .

Details

`npcdist` implements a variety of methods for estimating multivariate conditional cumulative distributions ($p+q$ -variate) defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2004) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the cumulative conditional distribution

at the point x . Generalized nearest-neighbor bandwidths change with the point at which the cumulative conditional distribution is estimated, x . Fixed bandwidths are constant over the support of x .

Training and evaluation input data may be a mix of continuous (default), unordered discrete (to be specified in the data frames using `factor`), and ordered discrete (to be specified in the data frames using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

`npcdist` returns a `condistribution` object. The generic accessor functions `fitted`, `se`, and `gradients`, extract estimated values, asymptotic standard errors on estimates, and gradients, respectively, from the returned object. Furthermore, the functions `predict`, `summary` and `plot` support objects of both classes. The returned objects have the following components:

<code>xbw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the explanatory data, <code>txdat</code>
<code>ybw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the dependent data, <code>tydat</code>
<code>xeval</code>	the evaluation points of the explanatory data
<code>yeval</code>	the evaluation points of the dependent data
<code>condist</code>	estimates of the conditional cumulative distribution at the evaluation points
<code>conderr</code>	standard errors of the cumulative conditional distribution estimates
<code>congrad</code>	if invoked with <code>gradients = TRUE</code> , estimates of the gradients at the evaluation points
<code>congerr</code>	if invoked with <code>gradients = TRUE</code> , standard errors of the gradients at the evaluation points
<code>log_likelihood</code>	log likelihood of the cumulative conditional distribution estimate

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

```

Arguments

formula a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.

data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
gdata	a grid of data on which the indicator function for least-squares cross-validation is to be computed (can be the sample or a grid of quantiles).
xdat	a p -variate data frame of explanatory data on which bandwidth selection will be performed. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
ydat	a q -variate data frame of dependent data on which bandwidth selection will be performed. The data types may be continuous, discrete (ordered factors), or some combination thereof.
gydat	a grid of data on which the indicator function for least-squares cross-validation is to be computed (can be the sample or a grid of quantiles for ydat).
bws	a bandwidth specification. This can be set as a <code>condbandwidth</code> object returned from a previous invocation, or as a $p+q$ -vector of bandwidths, with each element i up to $i = q$ corresponding to the bandwidth for column i in ydat, and each element i from $i = q + 1$ to $i = p + q$ corresponding to the bandwidth for column $i - q$ in xdat. In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
...	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.
bwmethod	which method to use to select bandwidths. <code>cv.ls</code> specifies least-squares cross-validation (Li, Lin and Racine (2013), and <code>normal-reference</code> just computes the ‘rule-of-thumb’ bandwidth h_j using the standard formula $h_j = 1.06\sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation, mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. Note that when there exist factors and the normal-reference rule is used, there is zero smoothing of the factors. Defaults to <code>cv.ls</code> .
bwscaling	a logical value that when set to TRUE the supplied bandwidths are interpreted as ‘scale factors’ (c_j), otherwise when the value is FALSE they are interpreted as ‘raw bandwidths’ (h_j for continuous data types, λ_j for discrete data types). For

continuous data types, c_j and h_j are related by the formula $h_j = c_j \sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of continuous variable j defined as $\min(\text{standard deviation}, \text{mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(2P+l)}$, where here j denotes discrete variable j . Defaults to FALSE.

bwtype	character string used for the continuous variable bandwidth type, specifying the type of bandwidth to compute and return in the <code>condbandwidth</code> object. Defaults to <code>fixed</code> . Option summary: <code>fixed</code> : compute fixed bandwidths <code>generalized_nn</code> : compute generalized nearest neighbors <code>adaptive_nn</code> : compute adaptive nearest neighbors
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to <code>FALSE</code> , a <code>condbandwidth</code> object will be returned with bandwidths set to those specified in <code>bws</code> . Defaults to <code>TRUE</code> .
cxkertype	character string used to specify the continuous kernel type for <code>xdat</code> . Can be set as <code>gaussian</code> , <code>epanechnikov</code> , or <code>uniform</code> . Defaults to <code>gaussian</code> .
cxkerorder	numeric value specifying kernel order for <code>xdat</code> (one of (2, 4, 6, 8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
cykertype	character string used to specify the continuous kernel type for <code>ydat</code> . Can be set as <code>gaussian</code> , <code>epanechnikov</code> , or <code>uniform</code> . Defaults to <code>gaussian</code> .
cykerorder	numeric value specifying kernel order for <code>ydat</code> (one of (2, 4, 6, 8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
uxkertype	character string used to specify the unordered categorical kernel type. Can be set as <code>aitchisonaitken</code> or <code>liracine</code> . Defaults to <code>aitchisonaitken</code> .
oxkertype	character string used to specify the ordered categorical kernel type. Can be set as <code>wangvanryzin</code> or <code>liracine</code> . Defaults to <code>liracine</code> .
oykertype	character string used to specify the ordered categorical kernel type. Can be set as <code>wangvanryzin</code> or <code>liracine</code> .
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points
remin	a logical value which when set as <code>TRUE</code> the search routine restarts from located minima for a minor gain in accuracy. Defaults to <code>TRUE</code> .
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
do.full.integral	a logical value which when set as <code>TRUE</code> evaluates the moment-based integral on the entire sample.
ngrid	integer number of grid points to use when computing the moment-based integral. Defaults to 100.

<code>ftol</code>	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01*\text{sqrt}(\text{.Machine}\$double.eps)$).
<code>tol</code>	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine's floating point precision). Defaults to $1.490116e-04$ ($1.0e+04*\text{sqrt}(\text{.Machine}\$double.eps)$).
<code>small</code>	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\text{sqrt}(\text{epsilon})$ times its central value, a fractional width of only about 10^{-04} (single precision) or 3×10^{-8} (double precision)). Defaults to $1.490116e-05$ ($1.0e+03*\text{sqrt}(\text{.Machine}\$double.eps)$).
<code>lbc.dir,dfc.dir,cfac.dir,initc.dir</code>	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
<code>lbd.dir,hbd.dir,dfac.dir,initd.dir</code>	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details
<code>lbc.init, hbc.init, cfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for numeric variables for Powell's algorithm. See Details
<code>lbd.init, hbd.init, dfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for categorical variables for Powell's algorithm. See Details
<code>scale.init.categorical.sample</code>	a logical value that when set to TRUE scales <code>lbd.dir</code> , <code>hbd.dir</code> , <code>dfac.dir</code> , and <code>initd.dir</code> by $n^{-2/(2P+l)}$, n the number of observations, P the order of the kernel, and l the number of numeric variables. See Details
<code>memfac</code>	The algorithm to compute the least-squares objective function uses a block-based algorithm to eliminate or minimize redundant kernel evaluations. Due to memory, hardware and software constraints, a maximum block size must be imposed by the algorithm. This block size is roughly equal to $\text{memfac} \times 10^5$ elements. Empirical tests on modern hardware find that a <code>memfac</code> of around 500 performs well. If you experience out of memory errors, or strange behaviour for large data sets (>100k elements) setting <code>memfac</code> to a lower value may fix the problem.

Details

`npcdistbw` implements a variety of methods for choosing bandwidths for multivariate distributions ($p + q$ -variate) defined over a set of possibly continuous and/or discrete (unordered `xdat`, ordered `xdat` and `ydat`) data. The approach is based on Li and Racine (2004) who employ 'generalized product kernels' that admit a mix of continuous and discrete data types.

The cross-validation methods employ multivariate numerical search algorithms (direction set (Powell's) methods in multidimensions).

Bandwidths can (and will) differ for each variable which is, of course, desirable.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change

with each sample realization in the set, x_i , when estimating the cumulative distribution at the point x . Generalized nearest-neighbor bandwidths change with the point at which the cumulative distribution is estimated, x . Fixed bandwidths are constant over the support of x .

npdistbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the `xdat` and `ydat` parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `xdat` may be a mix of continuous (default), unordered discrete (to be specified in the data frames using `factor`), and ordered discrete (to be specified in the data frames using `ordered`). Data contained in the data frame `ydat` may be a mix of continuous (default) and ordered discrete (to be specified in the data frames using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form dependent data \sim explanatory data, where dependent data and explanatory data are both series of variables specified by name, separated by the separation character '+'. For example, `y1 + y2 ~ x1 + x2` specifies that the bandwidths for the joint distribution of variables `y1` and `y2` conditioned on `x1` and `x2` are to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The optimizer invoked for search is Powell's conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and, when restarting, random values for successive invocations. Bandwidths for numeric variables are scaled by robust measures of spread, the sample size, and the number of numeric variables where appropriate. Two sets of parameters for bandwidths for numeric can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell's algorithm does not involve explicit computation of the function's gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable 'tuning' for various methods rather than for the user themselves.

Value

npdistbw returns a `condbandwidth` object, with the following components:

<code>xbw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the explanatory data, <code>xdat</code>
<code>ybw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the dependent data, <code>ydat</code>
<code>fval</code>	objective function value at minimum

if `bwtype` is set to `fixed`, an object containing bandwidths (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors

are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables.

The functions `predict`, `summary` and `plot` support objects of type `condbandwidth`.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(xdat,ydat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

npcmstest

*Kernel Consistent Model Specification Test with Mixed Data Types***Description**

npcmstest implements a consistent test for correct specification of parametric regression models (linear or nonlinear) as described in Hsiao, Li, and Racine (2007).

Usage

```
npcmstest(formula,
          data = NULL,
          subset,
          xdat,
          ydat,
          model = stop(paste(sQuote("model"), " has not been provided")),
          distribution = c("bootstrap", "asymptotic"),
          boot.method = c("iid", "wild", "wild-rademacher"),
          boot.num = 399,
          pivot = TRUE,
          density.weighted = TRUE,
          random.seed = 42,
          ...)
```

Arguments

formula	a symbolic description of variables on which the test is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used.
model	a model object obtained from a call to <code>lm</code> (or <code>glm</code>). Important: the call to either <code>glm</code> or <code>lm</code> must have the arguments <code>x=TRUE</code> and <code>y=TRUE</code> or <code>npcmstest</code> will not work. Also, the test is based on residual bootstrapping hence the outcome must be continuous (which rules out Logit, Probit, and Count models).
xdat	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators.
ydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
distribution	a character string used to specify the method of estimating the distribution of the statistic to be calculated. <code>bootstrap</code> will conduct bootstrapping. <code>asymptotic</code> will use the normal distribution. Defaults to <code>bootstrap</code> .

<code>boot.method</code>	a character string used to specify the bootstrap method. <code>iid</code> will generate independent identically distributed draws. <code>wild</code> will use a wild bootstrap. <code>wild-rademacher</code> will use a wild bootstrap with Rademacher variables. Defaults to <code>iid</code> .
<code>boot.num</code>	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
<code>pivot</code>	a logical value specifying whether the statistic should be normalised such that it approaches $N(0, 1)$ in distribution. Defaults to <code>TRUE</code> .
<code>density.weighted</code>	a logical value specifying whether the statistic should be weighted by the density of <code>xdat</code> . Defaults to <code>TRUE</code> .
<code>random.seed</code>	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.
<code>...</code>	additional arguments supplied to control bandwidth selection on the residuals. One can specify the bandwidth type, kernel types, and so on. To do this, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> , as described in npregbw . This is necessary if you specify <code>bws</code> as a p -vector and not a bandwidth object, and you do not desire the default behaviours.

Value

`npcmstest` returns an object of type `cmstest` with the following components, components will contain information related to J_n or I_n depending on the value of `pivot`:

<code>Jn</code>	the statistic J_n
<code>In</code>	the statistic I_n
<code>Omega.hat</code>	as described in Hsiao, C. and Q. Li and J.S. Racine.
<code>q.*</code>	the various quantiles of the statistic J_n (or I_n if <code>pivot=FALSE</code>) are in components <code>q.90</code> , <code>q.95</code> , <code>q.99</code> (one-sided 1%, 5%, 10% critical values)
<code>P</code>	the P-value of the statistic
<code>Jn.bootstrap</code>	if <code>pivot=TRUE</code> contains the bootstrap replications of J_n
<code>In.bootstrap</code>	if <code>pivot=FALSE</code> contains the bootstrap replications of I_n

[summary](#) supports object of type `cmstest`.

Usage Issues

`npcmstest` supports regression objects generated by `lm` and uses features specific to objects of type `lm` hence if you attempt to pass objects of a different type the function cannot be expected to work.

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

## End(Not run)
```

Description

npconmode performs kernel modal regression on mixed data, and finds the conditional mode given a set of training data, consisting of explanatory data and dependent data, and possibly evaluation data. Automatically computes various in sample and out of sample measures of accuracy.

Usage

```
npconmode(bws, ...)

## S3 method for class 'formula'
npconmode(bws, data = NULL, newdata = NULL, ...)

## S3 method for class 'call'
npconmode(bws, ...)

## Default S3 method:
npconmode(bws, txdat, tydat, ...)

## S3 method for class 'conbandwidth'
npconmode(bws,
          txdat = stop("invoked without training data 'txdat'"),
          tydat = stop("invoked without training data 'tydat'"),
          exdat,
          eydat,
          ...)
```

Arguments

bws	a bandwidth specification. This can be set as a conbandwidth object returned from an invocation of npcdensbw
...	additional arguments supplied to specify the bandwidth type, kernel types, and so on, detailed below. This is necessary if you specify bws as a $p + q$ -vector and not a conbandwidth object, and you do not desire the default behaviours.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from environment(bws), typically the environment from which npcdensbw was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
txdat	a p -variate data frame of explanatory data (conditioning data) used to calculate the regression estimators. Defaults to the training data used to compute the bandwidth object.
tydat	a one (1) dimensional vector of unordered or ordered factors, containing the dependent data. Defaults to the training data used to compute the bandwidth object.

exdat	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by txdat.
eydat	a one (1) dimensional numeric or integer vector of the true values (outcomes) of the dependent variable. By default, evaluation takes place on the data provided by tydat.

Value

npconmode returns a conmode object with the following components:

conmode	a vector of type factor (or ordered factor) containing the conditional mode at each evaluation point
condens	a vector of numeric type containing the modal density estimates at each evaluation point
xeval	a data frame of evaluation points
yeval	a vector of type factor (or ordered factor) containing the actual outcomes, or NA if not provided
confusion.matrix	the confusion matrix or NA if outcomes are not available
CCR.overall	the overall correct classification ratio, or NA if outcomes are not available
CCR.byoutcome	a numeric vector containing the correct classification ratio by outcome, or NA if outcomes are not available
fit.mcfadden	the McFadden-Puig-Kerschner performance measure or NA if outcomes are not available

The functions `mode`, and `fitted` may be used to extract the conditional mode estimates, and the conditional density estimates at the conditional mode, respectively, from the resulting object. Also, `summary` supports conmode objects.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

## End(Not run)

```

Description

npcopula implements the nonparametric mixed data kernel copula approach of Racine (2015) for an arbitrary number of dimensions

Usage

```
npcopula(bws,
         data,
         u = NULL,
         n.quasi.inv = 1000,
         er.quasi.inv = 1)
```

Arguments

<code>bws</code>	an unconditional joint distribution (<code>npudistbw</code>) or joint density (<code>npudensbw</code>) bandwidth object (if <code>bws</code> is delivered via <code>npudistbw</code> the copula distribution is estimated, while if <code>bws</code> is delivered via <code>npudensbw</code> the copula density is estimated)
<code>data</code>	a data frame containing variables used to construct <code>bws</code>
<code>u</code>	an optional matrix of real numbers lying in $[0,1]$, each column of which corresponds to the vector of <code>u</code> th quantile values desired for each variable in the copula (otherwise the <code>u</code> values returned are those corresponding to the sample realizations)
<code>n.quasi.inv</code>	number of grid points generated when <code>u</code> is provided in order to compute the quasi-inverse of each marginal distribution (see details)
<code>er.quasi.inv</code>	number passed to <code>extendrange</code> when <code>u</code> is provided specifying the fraction by which the data range should be extended when constructing the grid used to compute the quasi-inverse (see details)

Details

`npcopula` computes the nonparametric copula or copula density using inversion (Nelsen (2006), page 51). For the inversion approach, we exploit Sklar's theorem (Corollary 2.3.7, Nelsen (2006)) to produce copulas directly from the joint distribution function using $C(u, v) = H(F^{-1}(u), G^{-1}(v))$ rather than the typical approach that instead uses $H(x, y) = C(F(x), G(y))$. Whereas the latter requires kernel density estimation on a d -dimensional unit hypercube which necessitates the use of boundary correction methods, the former does not.

Note that if `u` is provided then `expand.grid` is called on `u`. As the dimension increases this can become unwieldy and potentially consume an enormous amount of memory unless the number of grid points is kept very small. Given that computing the copula on a grid is typically done for graphical purposes, providing `u` is typically done for two-dimensional problems only. Even here, however, providing a grid of length 100 will expand into a matrix of dimension 10000 by 2 which, though not memory intensive, may be computationally burdensome.

The 'quasi-inverse' is computed via Definition 2.3.6 from Nelsen (2006). We compute an equi-quantile grid on the range of the data of length `n.quasi.inv/2`. We then extend the range of the data by the factor `er.quasi.inv` and compute an equi-spaced grid of points of length `n.quasi.inv/2` (e.g. using the default `er.quasi.inv=1` we go from the minimum data value minus $1 \times$ the range to the maximum data value plus $1 \times$ the range for each marginal). We then take these two grids, concatenate and sort, and these form the final grid of length `n.quasi.inv` for computing the quasi-inverse.

Note that if `u` is provided and any elements of (the columns of) `u` are such that they lie beyond the respective values of F for the evaluation data for the respective marginal, such values are reset to the

minimum/maximum values of F for the respective marginal. It is therefore prudent to inspect the values of u returned by `npcopula` when u is provided.

Note that copula are only defined for data of type `numeric` or `ordered`.

Value

`npcopula` returns an object of type `data.frame` with the following components

<code>copula</code>	the copula (bandwidth object obtained from <code>npudistbw</code>) or copula density (bandwidth object obtained from <code>npudensbw</code>)
<code>u</code>	the matrix of marginal u values associated with the sample realizations (<code>u=NULL</code>) or those created via <code>expand.grid</code> when u is provided
<code>data</code>	the matrix of marginal quantiles constructed when u is provided (data returned has the same names as data inputted)

Usage Issues

See the example below for proper usage.

npdeneqtest

Kernel Consistent Density Equality Test with Mixed Data Types

Description

npdeneqtest implements a consistent integrated squared difference test for equality of densities as described in Li, Maasoumi, and Racine (2009).

Usage

```

npdeneqtest(x = NULL,
            y = NULL,
            bw.x = NULL,
            bw.y = NULL,
            boot.num = 399,
            random.seed = 42,
            ...)

```

Arguments

<code>x, y</code>	data frames for the two samples for which one wishes to test equality of densities. The variables in each data frame must be the same (i.e. have identical names).
<code>bw.x, bw.y</code>	optional bandwidth objects for <code>x, y</code>
<code>boot.num</code>	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
<code>random.seed</code>	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.
<code>...</code>	additional arguments supplied to specify the bandwidth type, kernel types, and so on. This is used if you do not pass in bandwidth objects and you do not desire the default behaviours. To do this, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> .

Details

npdeneqtest computes the integrated squared density difference between the estimated densities/probabilities of two samples having identical variables/datatypes. See Li, Maasoumi, and Racine (2009) for details.

Value

npdeneqtest returns an object of type `deneqtest` with the following components

<code>Tn</code>	the (standardized) statistic T_n
<code>In</code>	the (unstandardized) statistic I_n
<code>Tn.bootstrap</code>	contains the bootstrap replications of T_n
<code>In.bootstrap</code>	contains the bootstrap replications of I_n
<code>Tn.P</code>	the P-value of the T_n statistic
<code>In.P</code>	the P-value of the I_n statistic
<code>boot.num</code>	number of bootstrap replications

[summary](#) supports object of type `deneqtest`.

Usage Issues

If you are using data of mixed types, then it is advisable to use the [data.frame](#) function to construct your input data and not [cbind](#), since [cbind](#) will typically not work as intended on mixed data types and will coerce the data to the same type.

It is crucial that both data frames have the same variable names.

npdeptest

Kernel Consistent Pairwise Nonlinear Dependence Test for Univariate Processes

Description

npdeptest implements the consistent metric entropy test of pairwise independence as described in Maasoumi and Racine (2002).

Usage

```

npdeptest(data.x = NULL,
          data.y = NULL,
          method = c("integration","summation"),
          bootstrap = TRUE,
          boot.num = 399,
          random.seed = 42)

```

Arguments

`data.x`, `data.y` two univariate vectors containing two variables that are of type `numeric`.

method	a character string used to specify whether to compute the integral version or the summation version of the statistic. Can be set as <code>integration</code> or <code>summation</code> (see below for details). Defaults to <code>integration</code> .
bootstrap	a logical value which specifies whether to conduct the bootstrap test or not. If set to <code>FALSE</code> , only the statistic will be computed. Defaults to <code>TRUE</code> .
boot.num	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
random.seed	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.

Details

`npsdeptest` computes the nonparametric metric entropy (normalized Hellinger of Granger, Maasoumi and Racine (2004)) for testing pairwise nonlinear dependence between the densities of two data series. See Maasoumi and Racine (2002) for details. Default bandwidths are of the Kullback-Leibler variety obtained via likelihood cross-validation. The null distribution is obtained via bootstrap resampling under the null of pairwise independence.

`npdeptest` computes the distance between the joint distribution and the product of marginals (i.e. the joint distribution under the null), $D[f(y, \hat{y}), f(y) \times f(\hat{y})]$. Examples include, (a) a measure/test of “fit”, for in-sample values of a variable y and its fitted values, \hat{y} , and (b) a measure of “predictability” for a variable y and its predicted values \hat{y} (from a user implemented model).

The summation version of this statistic will be numerically unstable when `data.x` and `data.y` lack common support or are sparse (the summation version involves division of densities while the integration version involves differences). Warning messages are produced should this occur (‘integration recommended’) and should be heeded.

Value

`npdeptest` returns an object of type `deptest` with the following components

<code>Srho</code>	the statistic <code>Srho</code>
<code>Srho.bootstrap.vec</code>	contains the bootstrap replications of <code>Srho</code>
<code>P</code>	the P-value of the <code>Srho</code> statistic
<code>bootstrap</code>	a logical value indicating whether bootstrapping was performed
<code>boot.num</code>	number of bootstrap replications
<code>bw.data.x</code>	the numeric bandwidth for <code>data.x</code> marginal density
<code>bw.data.y</code>	the numeric bandwidth for <code>data.y</code> marginal density
<code>bw.joint</code>	the numeric matrix of bandwidths for data and lagged data joint density at <code>lag.num.lag</code>

`summary` supports object of type `deptest`.

Usage Issues

The integration version of the statistic uses multidimensional numerical methods from the [cubature](#) package. See [adaptIntegrate](#) for details. The integration version of the statistic will be substantially slower than the summation version, however, it will likely be both more accurate and powerful.

npindex

Semiparametric Single Index Model

Description

npindex computes a semiparametric single index model for a dependent variable and p -variate explanatory data using the model $Y = G(X\beta) + \epsilon$, given a set of evaluation points, training points (consisting of explanatory data and dependent data), and a npindexbw bandwidth specification. Note that for this semiparametric estimator, the bandwidth object contains parameters for the single index model and the (scalar) bandwidth for the index function.

Usage

```

npindex(bws, ...)

## S3 method for class 'formula'
npindex(bws,
        data = NULL,
        newdata = NULL,
        y.eval = FALSE,
        ...)

```

```

## S3 method for class 'call'
npindex(bws,
        ...)

## Default S3 method:
npindex(bws,
        txdat,
        tydat,
        ...)

## S3 method for class 'sibandwidth'
npindex(bws,
        txdat = stop("training data 'txdat' missing"),
        tydat = stop("training data 'tydat' missing"),
        exdat,
        eydat,
        gradients = FALSE,
        residuals = FALSE,
        errors = FALSE,
        boot.num = 399,
        ...)

```

Arguments

<code>bws</code>	a bandwidth specification. This can be set as a <code>sibandwidth</code> object returned from an invocation of <code>npindexbw</code> , or as a vector of parameters (beta) with each element i corresponding to the coefficient for column i in <code>txdat</code> where the first element is normalized to 1, and a scalar bandwidth (h).
<code>gradients</code>	a logical value indicating that you want gradients and the asymptotic covariance matrix for beta computed and returned in the resulting <code>singleindex</code> object. Defaults to FALSE.
<code>residuals</code>	a logical value indicating that you want residuals computed and returned in the resulting <code>singleindex</code> object. Defaults to FALSE.
<code>errors</code>	a logical value indicating that you want (bootstrapped) standard errors for the conditional mean, gradients (when <code>gradients=TRUE</code> is set), and average gradients (when <code>gradients=TRUE</code> is set), computed and returned in the resulting <code>singleindex</code> object. Defaults to FALSE.
<code>boot.num</code>	an integer specifying the number of bootstrap replications to use when performing standard error calculations. Defaults to 399.
<code>...</code>	additional arguments supplied to specify the parameters to the <code>sibandwidth</code> S3 method, which is called during estimation.
<code>data</code>	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npindexbw</code> was called.
<code>newdata</code>	An optional data frame in which to look for evaluation data. If omitted, the training data are used.

<code>y.eval</code>	If <code>newdata</code> contains dependent data and <code>y.eval = TRUE</code> , <code>np</code> will compute goodness of fit statistics on these data and return them. Defaults to <code>FALSE</code> .
<code>txdat</code>	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators. Defaults to the training data used to compute the bandwidth object.
<code>tydat</code>	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>txdat</code> . Defaults to the training data used to compute the bandwidth object.
<code>exdat</code>	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>txdat</code> .
<code>eydat</code>	a one (1) dimensional numeric or integer vector of the true values of the dependent variable. Optional, and used only to calculate the true errors.

Details

A matrix of gradients along with average derivatives are computed and returned if `gradients=TRUE` is used.

Value

`npindex` returns a `npsingleindex` object. The generic functions `fitted`, `residuals`, `coef`, `vcov`, `se`, `predict`, and `gradients`, extract (or generate) estimated values, residuals, coefficients, variance-covariance matrix, bootstrapped standard errors on estimates, predictions, and gradients, respectively, from the returned object. Furthermore, the functions `summary` and `plot` support objects of this type. The returned object has the following components:

<code>eval</code>	evaluation points
<code>mean</code>	estimates of the regression function (conditional mean) at the evaluation points
<code>beta</code>	the model coefficients
<code>betavcov</code>	the asymptotic covariance matrix for the model coefficients
<code>merr</code>	standard errors of the regression function estimates
<code>grad</code>	estimates of the gradients at each evaluation point
<code>gerr</code>	standard errors of the gradient estimates
<code>mean.grad</code>	mean (average) gradient over the evaluation points
<code>mean.gerr</code>	bootstrapped standard error of the mean gradient estimates
<code>R2</code>	if <code>method="ichimura"</code> , coefficient of determination (Doksum and Samarov (1995))
<code>MSE</code>	if <code>method="ichimura"</code> , mean squared error
<code>MAE</code>	if <code>method="ichimura"</code> , mean absolute error
<code>MAPE</code>	if <code>method="ichimura"</code> , mean absolute percentage error
<code>CORR</code>	if <code>method="ichimura"</code> , absolute value of Pearson's correlation coefficient
<code>SIGN</code>	if <code>method="ichimura"</code> , fraction of observations where fitted and observed values agree in sign

<code>confusion.matrix</code>	if <code>method="kleinspady"</code> , the confusion matrix or NA if outcomes are not available
<code>CCR.overall</code>	if <code>method="kleinspady"</code> , the overall correct classification ratio, or NA if outcomes are not available
<code>CCR.byoutcome</code>	if <code>method="kleinspady"</code> , a numeric vector containing the correct classification ratio by outcome, or NA if outcomes are not available
<code>fit.mcfadden</code>	if <code>method="kleinspady"</code> , the McFadden-Puig-Kerschner performance measure or NA if outcomes are not available

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

`vcov` requires that `gradients=TRUE` be set.

npindexbw

Semiparametric Single Index Model Parameter and Bandwidth Selection

Description

npindexbw computes a npindexbw bandwidth specification using the model $Y = G(X\beta) + \epsilon$. For continuous Y , the approach is that of Hardle, Hall and Ichimura (1993) which jointly minimizes a least-squares cross-validation function with respect to the parameters and bandwidth. For binary Y , a likelihood-based cross-validation approach is employed which jointly maximizes a likelihood cross-validation function with respect to the parameters and bandwidth. The bandwidth object contains parameters for the single index model and the (scalar) bandwidth for the index function.

Usage

```

npindexbw(...)

## S3 method for class 'formula'
npindexbw(formula, data, subset, na.action, call, ...)

## S3 method for class 'NULL'
npindexbw(xdat = stop("training data xdat missing"),
          ydat = stop("training data ydat missing"),
          bws,
          ...)

## Default S3 method:
npindexbw(xdat = stop("training data xdat missing"),
          ydat = stop("training data ydat missing"),
          bws,
          bandwidth.compute = TRUE,
          nmulti,
          random.seed,
          optim.method,

```

```

    optim.maxattempts,
    optim.reltol,
    optim.abstol,
    optim.maxit,
    only.optimize.beta,
    ...)

## S3 method for class 'sibandwidth'
npindexbw(xdat = stop("training data xdat missing"),
          ydat = stop("training data ydat missing"),
          bws,
          bandwidth.compute = TRUE,
          nmulti,
          random.seed = 42,
          optim.method = c("Nelder-Mead", "BFGS", "CG"),
          optim.maxattempts = 10,
          optim.reltol = sqrt(.Machine$double.eps),
          optim.abstol = .Machine$double.eps,
          optim.maxit = 500,
          only.optimize.beta = FALSE,
          ...)

```

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
xdat	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators.
ydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
bws	a bandwidth specification. This can be set as a <code>singleindexbandwidth</code> object returned from an invocation of <code>npindexbw</code> , or as a vector of parameters (beta) with each element i corresponding to the coefficient for column i in <code>xdat</code> where the first element is normalized to 1, and a scalar bandwidth (h). If specified

	as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, and so on.
method	the single index model method, one of either “ichimura” (Ichimura (1993)) or “kleinspady” (Klein and Spady (1993)). Defaults to <code>ichimura</code> .
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points. Defaults to <code>min(5, ncol(xdat))</code> .
random.seed	an integer used to seed R’s random number generator. This ensures replicability of the numerical search. Defaults to 42.
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to <code>FALSE</code> , a bandwidth object will be returned with bandwidths set to those specified in <code>bws</code> . Defaults to <code>TRUE</code> .
optim.method	method used by <code>optim</code> for minimization of the objective function. See <code>?optim</code> for references. Defaults to “Nelder-Mead”. the default method is an implementation of that of Nelder and Mead (1965), that uses only function values and is robust but relatively slow. It will work reasonably well for non-differentiable functions. method “BFGS” is a quasi-Newton method (also known as a variable metric algorithm), specifically that published simultaneously in 1970 by Broyden, Fletcher, Goldfarb and Shanno. This uses function values and gradients to build up a picture of the surface to be optimized. method “CG” is a conjugate gradients method based on that by Fletcher and Reeves (1964) (but with the option of Polak-Ribiere or Beale-Sorenson updates). Conjugate gradient methods will generally be more fragile than the BFGS method, but as they do not store a matrix they may be successful in much larger optimization problems.
optim.maxattempts	maximum number of attempts taken trying to achieve successful convergence in <code>optim</code> . Defaults to 100.
optim.abstol	the absolute convergence tolerance used by <code>optim</code> . Only useful for non-negative functions, as a tolerance for reaching zero. Defaults to <code>.Machine\$double.eps</code> .
optim.reltol	relative convergence tolerance used by <code>optim</code> . The algorithm stops if it is unable to reduce the value by a factor of <code>'reltol * (abs(val) + reltol)'</code> at a step. Defaults to <code>sqrt(.Machine\$double.eps)</code> , typically about <code>1e-8</code> .
optim.maxit	maximum number of iterations used by <code>optim</code> . Defaults to 500.
only.optimize.beta	signals the routine to only minimize the objective function with respect to beta
...	additional arguments supplied to specify the parameters to the <code>sibandwidth S3</code> method, which is called during the numerical search.

Details

We implement Ichimura’s (1993) method via joint estimation of the bandwidth and coefficient vector using leave-one-out nonlinear least squares. We implement Klein and Spady’s (1993) method

maximizing the leave-one-out log likelihood function jointly with respect to the bandwidth and coefficient vector. Note that Klein and Spady's (1993) method is for *binary outcomes only*, while Ichimura's (1993) method can be applied for any outcome data type (i.e., continuous or discrete).

We impose the identification condition that the first element of the coefficient vector β is equal to one, while identification also requires that the explanatory variables contain *at least one* continuous variable.

npindexbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the xdat and ydat parameters. Use of these two interfaces is **mutually exclusive**.

Note that, unlike most other bandwidth methods in the np package, this implementation uses the R `optim` nonlinear minimization routines and `npksum`. We have implemented multistarting and strongly encourage its use in practice. For exploratory purposes, you may wish to override the default search tolerances, say, setting `optim.reltol=.1` and conduct multistarting (the default is to restart `min(5, ncol(xdat))` times) as is done for a number of examples.

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form `dependent data ~ explanatory data`, where `dependent data` is a univariate response, and `explanatory data` is a series of variables specified by name, separated by the separation character `'+'`. For example `y1 ~ x1 + x2` specifies that the bandwidth object for the regression of response `y1` and semiparametric regressors `x1` and `x2` are to be estimated. See below for further examples.

Value

npindexbw returns a sibandwidth object, with the following components:

bw	bandwidth(s), scale factor(s) or nearest neighbours for the data, xdat
beta	coefficients of the model
fval	objective function value at minimum

If `bwtype` is set to `fixed`, an object containing a scalar bandwidth for the function $G(X\beta)$ and an estimate of the parameter vector β is returned.

If `bwtype` is set to `generalized_nn` or `adaptive_nn`, then instead the scalar k th nearest neighbor is returned.

The functions `coef`, `predict`, `summary`, and `plot` support objects of this class.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may*

often be necessary. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `optim.reltol=.1` and conduct multistarting (the default is to restart `min(5, ncol(xdat))` times). Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

      ...)

```

Arguments

formula	a symbolic description of variables on which the sum is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
newdata	An optional data frame in which to look for evaluation data. If omitted, data is used.
subset	an optional vector specifying a subset of observations to be used.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
...	additional arguments supplied to specify the parameters to the default S3 method, which is called during estimation.
txdat	a p -variate data frame of sample realizations (training data) used to compute the sum.
tydat	a numeric vector of data to be weighted. The i th kernel weight is applied to the i th element. Defaults to 1.
exdat	a p -variate data frame of sum evaluation points (if omitted, defaults to the training data itself).
bws	a bandwidth specification. This can be set as any suitable bandwidth object returned from a bandwidth-generating function, or a numeric vector.

<code>weights</code>	a n by q matrix of weights which can optionally be applied to <code>tydat</code> in the sum. See details.
<code>leave.one.out</code>	a logical value to specify whether or not to compute the leave one out sums. Will not work if <code>exdat</code> is specified. Defaults to <code>FALSE</code> .
<code>kernel.pow</code>	an integer specifying the power to which the kernels will be raised in the sum. Defaults to 1.
<code>bandwidth.divide</code>	a logical specifying whether or not to divide continuous kernel weights by their bandwidths. Use this with nearest-neighbor methods. Defaults to <code>FALSE</code> .
<code>operator</code>	a string specifying whether the normal, convolution, derivative, or integral kernels are to be used. Operators scale results by factors of h or $1/h$ where appropriate. Defaults to <code>normal</code> and applies to all elements in a multivariate object. See details.
<code>permutation.operator</code>	a string which can have a value of <code>none</code> , <code>normal</code> , <code>derivative</code> , or <code>integral</code> . If set to something other than <code>none</code> (the default), then a separate result will be returned for each term in the product kernel, with the operator applied to that term. Permutation operators scale results by factors of h or $1/h$ where appropriate. This is useful for computing gradients, for example.
<code>compute.score</code>	a logical specifying whether or not to return the score (the ‘grad h’ terms) for each dimension in addition to the kernel sum. Cannot be <code>TRUE</code> if a permutation operator other than “none” is selected.
<code>compute.ocg</code>	a logical specifying whether or not to return a separate result for each unordered and ordered dimension, where the product kernel term for that dimension is evaluated at an appropriate reference category. This is used primarily in <code>np</code> to compute ordered and unordered categorical gradients. See details.
<code>return.kernel.weights</code>	a logical specifying whether or not to return the matrix of generalized product kernel weights. Defaults to <code>FALSE</code> . See details.

Details

`npksum` exists so that you can create your own kernel objects with or without a variable to be weighted (default $Y = 1$). With the options available, you could create new nonparametric tests or even new kernel estimators. The convolution kernel option would allow you to create, say, the least squares cross-validation function for kernel density estimation.

`npksum` uses highly-optimized C code that strives to minimize its ‘memory footprint’, while there is low overhead involved when using repeated calls to this function (see, by way of illustration, the example below that conducts leave-one-out cross-validation for a local constant regression estimator via calls to the R function `nlm`, and compares this to the `npregbw` function).

`npksum` implements a variety of methods for computing multivariate kernel sums (p -variate) defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change

with each sample realization in the set, x_i , when estimating the kernel sum at the point x . Generalized nearest-neighbor bandwidths change with the point at which the sum is computed, x . Fixed bandwidths are constant over the support of x .

npksum computes $\sum_{j=1}^n W_j' Y_j K(X_j)$, where W_j represents a row vector extracted from W . That is, it computes the kernel weighted sum of the outer product of the rows of W and Y . In the examples, the uses of such sums are illustrated.

npksum may be invoked *either* with a formula-like symbolic description of variables on which the sum is to be performed *or* through a simpler interface whereby data is passed directly to the function via the `txdat` and `tydat` parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `txdat` (and also `exdat`) may be a mix of continuous (default), unordered discrete (to be specified in the data frame `txdat` using the `factor` command), and ordered discrete (to be specified in the data frame `txdat` using the `ordered` command). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form `dependent data ~ explanatory data`, where `dependent data` and `explanatory data` are both series of variables specified by name, separated by the separation character `'+'`. For example, `y1 ~ x1 + x2` specifies that `y1` is to be kernel-weighted by `x1` and `x2` throughout the sum. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel (see `np` for details).

The option `operator=` can be used to 'mix and match' operator strings to create a 'hybrid' kernel provided they match the dimension of the data. For example, for a two-dimensional data frame of `numeric` datatypes, `operator=c("normal", "derivative")` will use the normal (i.e. PDF) kernel for variable one and the derivative of the PDF kernel for variable two. Please note that applying operators will scale the results by factors of h or $1/h$ where appropriate.

The option `permutation.operator=` can be used to 'mix and match' operator strings to create a 'hybrid' kernel, in addition to the kernel sum with no operators applied, one for each continuous dimension in the data. For example, for a two-dimensional data frame of `numeric` datatypes, `permutation.operator=c("derivative")` will return the usual kernel sum as if `operator = c("normal", "normal")` in the `ksum` member, and in the `p.ksum` member, it will return kernel sums for `operator = c("derivative", "normal")`, and `operator = c("normal", "derivative")`. This makes the computation of gradients much easier.

The option `compute.score=` can be used to compute the gradients with respect to h in addition to the normal kernel sum. Like permutations, the additional results are returned in the `p.ksum`. This option does not work in conjunction with `permutation.operator`.

The option `compute.ocg=` works much like `permutation.operator`, but for discrete variables. The kernel is evaluated at a reference category in each dimension: for ordered data, the next lowest category is selected, except in the case of the lowest category, where the second lowest category is selected; for unordered data, the first category is selected. These additional data are returned in the `p.ksum` member. This option can be set simultaneously with `permutation.operator`.

The option `return.kernel.weights=TRUE` returns a matrix of dimension 'number of training observations' by 'number of evaluation observations' and contains only the generalized product kernel

weights ignoring all other objects and options that may be provided to npksum (e.g. `bandwidth.divide=TRUE` will be ignored, etc.). Summing the columns of the weight matrix and dividing by ‘number of training observations’ times the product of the bandwidths (i.e. `colMeans(foo$kw)/prod(h)`) would produce the kernel estimator of a (multivariate) density (`operator="normal"`) or multivariate cumulative distribution (`operator="integral"`).

Value

npksum returns a npkernelsum object with the following components:

eval	the evaluation points
ksum	the sum at the evaluation points
kw	the kernel weights (when <code>return.kernel.weights=TRUE</code> is specified)

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

# EXAMPLE 4: For this example, we conduct least-squares cross-validation  
# for the local-constant regression estimator. We first write an R  
# function `ss' that computes the leave-one-out sum of squares using the  
# npksum() function, and then feed this function, along with  
# random starting values for the bandwidth vector, to the nlm() routine  
# in R (nlm = Non-Linear Minimization). Finally, we compare results with  
# the function npregbw() that is written solely in C and calls  
# a tightly coupled C-level search routine. Note that one could make  
# repeated calls to nlm() using different starting values for h (highly  
# recommended in general).  
  
# Increase the number of digits printed out by default in R and avoid  
# using scientific notation for this example (we wish to compare  
# objective function minima)  
  
options(scipen=100, digits=12)

npplot

General Purpose Plotting of Nonparametric Objects

Description

npplot is invoked by `plot` and generates plots of nonparametric statistical objects such as regressions, quantile regressions, partially linear regressions, single-index models, densities and distributions, given training data and a bandwidth object.

Usage

```

npplot(bws = stop("'bws' has not been set"), ..., random.seed = 42)

## S3 method for class 'bandwidth'
npplot(bws,
       xdat,
       data = NULL,

Arguments

<code>bws</code>	a bandwidth specification. This should be a bandwidth object returned from an invocation of <code>npudensbw</code> , <code>npcdensbw</code> , <code>npregbw</code> , <code>npplregbw</code> , <code>npindexbw</code> , or <code>npscoefbw</code> .
<code>...</code>	additional arguments supplied to control various aspects of plotting, depending on the type of object to be plotted, detailed below.
<code>data</code>	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment where the bandwidth object was generated.
<code>xdat</code>	a p -variate data frame of sample realizations (training data).
<code>ydat</code>	a q -variate data frame of sample realizations (training data). In a regression or conditional density context, this is the dependent data.

<code>zdat</code>	a p -variate data frame of sample realizations (training data).
<code>xq</code>	a numeric p -vector of quantiles. Each element i of <code>xq</code> corresponds to the i th column of <code>txdat</code> . Defaults to the median (0.5). See details.
<code>yq</code>	a numeric q -vector of quantiles. Each element i of <code>yq</code> corresponds to the i th column of <code>tydat</code> . Only to be specified in a conditional density context. Defaults to the median (0.5). See details.
<code>zq</code>	a numeric q -vector of quantiles. Each element i of <code>zq</code> corresponds to the i th column of <code>tzdat</code> . Only to be specified in a semiparametric model context. Defaults to the median (0.5). See details.
<code>xtrim</code>	a numeric p -vector of quantiles. Each element i of <code>xtrim</code> corresponds to the i th column of <code>txdat</code> . Defaults to \emptyset . \emptyset . See details.
<code>ytrim</code>	a numeric q -vector of quantiles. Each element i of <code>ytrim</code> corresponds to the i th column of <code>tydat</code> . Defaults to \emptyset . \emptyset . See details.
<code>ztrim</code>	a numeric q -vector of quantiles. Each element i of <code>ztrim</code> corresponds to the i th column of <code>tzdat</code> . Defaults to \emptyset . \emptyset . See details.
<code>neval</code>	an integer specifying the number of evaluation points. Only applies to continuous variables however, as discrete variables will be evaluated once at each category. Defaults to 50.
<code>common.scale</code>	a logical value specifying whether or not all graphs are to be plotted on a common scale. Defaults to TRUE.
<code>perspective</code>	a logical value specifying whether a perspective plot should be displayed (if possible). Defaults to TRUE.
<code>gradients</code>	a logical value specifying whether gradients should be plotted (if possible). Defaults to FALSE.
<code>main</code>	the title, see title
<code>type</code>	character indicating the type of plotting; actually any of the types as in plot.default
<code>ylim</code>	a two-element numeric vector of the minimum and maximum y plotting limits. Defaults to NULL.
<code>theta</code>	a numeric value specifying the starting azimuthal angle of the perspective plot. Defaults to \emptyset . \emptyset .
<code>phi</code>	a numeric value specifying the starting zenith angle of the perspective plot. Defaults to $1\emptyset$. \emptyset .
<code>tau</code>	a numeric value specifying the τ th quantile is desired when plotting quantile regressions.
<code>view</code>	a character string used to specify the viewing mode of the perspective plot. Can be set as <code>rotate</code> or <code>fixed</code> . Defaults to <code>rotate</code> .
<code>plot.behavior</code>	a character string used to specify the net behavior of <code>npplot</code> . Can be set as <code>plot</code> , <code>plot-data</code> or <code>data</code> . Defaults to <code>plot</code> . See value.
<code>plot.errors.method</code>	a character string used to specify the method to calculate errors. Can be set as <code>none</code> , <code>bootstrap</code> , or <code>asymptotic</code> . Defaults to <code>none</code> .
<code>plot.errors.boot.method</code>	a character string used to specify the bootstrap method. Can be set as <code>inid</code> , <code>fixed</code> , or <code>geom</code> (see below for details). Defaults to <code>inid</code> .

<code>plot.errors.boot.blocklen</code>	an integer used to specify the block length b for the fixed or geom bootstrap (see below for details).
<code>plot.errors.boot.num</code>	an integer used to specify the number of bootstrap samples to use for the calculation of errors. Defaults to 399.
<code>plot.errors.center</code>	a character string used to specify where to center the errors on the plot(s). Can be set as <code>estimate</code> or <code>bias-corrected</code> . Defaults to <code>estimate</code> .
<code>plot.errors.type</code>	a character string used to specify the type of error to calculate. Can be set as <code>standard</code> or <code>quantiles</code> . Defaults to <code>standard</code> .
<code>plot.errors.quantiles</code>	a numeric vector specifying the quantiles of the statistic to calculate for the purpose of error plotting. Defaults to <code>c(0.025, 0.975)</code> .
<code>plot.errors.style</code>	a character string used to specify the style of error plotting. Can be set as <code>bar</code> or <code>band</code> . Defaults to <code>bar</code> . Bands are not drawn for discrete variables.
<code>plot.errors.bar</code>	a character string used to specify the error bar shape. Can be set as <code> </code> (vertical bar character) for a dashed vertical bar, or as <code>I</code> for an 'I' shaped error bar with horizontal bounding bars. Defaults to <code> </code> .
<code>plot.errors.bar.num</code>	an integer specifying the number of error bars to plot. Defaults to <code>min(neval, 25)</code> .
<code>plot.bxp</code>	a logical value specifying whether boxplots should be produced when appropriate. Defaults to <code>FALSE</code> .
<code>plot.bxp.out</code>	a logical value specifying whether outliers should be plotted on boxplots. Defaults to <code>TRUE</code> .
<code>random.seed</code>	an integer used to seed R's random number generator. This ensures replicability of the bootstrapped errors. Defaults to 42.

Details

`nplot` is a general purpose plotting routine for visually exploring objects generated by the `np` library, such as regressions, quantile regressions, partially linear regressions, single-index models, densities and distributions. There is no need to call `nplot` directly as it is automatically invoked when `plot` is used with an object generated by the `np` package.

Visualizing one and two dimensional datasets is a straightforward process. The default behavior of `nplot` is to generate a standard 2D plot to visualize univariate data, and a perspective plot for bivariate data. When visualizing higher dimensional data, `nplot` resorts to plotting a series of 1D slices of the data. For a slice along dimension i , all other variables at indices $j \neq i$ are held constant at the quantiles specified in the j th element of `xq`. The default is the median.

The slice itself is evaluated on a uniformly spaced sequence of `neval` points. The interval of evaluation is determined by the training data. The default behavior is to evaluate from `min(txdat[, i])` to `max(txdat[, i])`. The `xtrim` variable allows for control over this behavior. When `xtrim` is set, data is evaluated from the `xtrim[i]`th quantile of `txdat[, i]` to the `1.0-xtrim[i]`th quantile of `txdat[, i]`.

Furthermore, `xtrim` can be set to a negative value in which case it will expand the limits of the evaluation interval beyond the support of the training data, by measuring the distance between `min(txdat[,i])` and the `xtrim[i]`th quantile of `txdat[,i]`, and extending the support by that distance on the lower limit of the interval. `npplot` uses an analogous procedure to extend the upper limit of the interval.

Bootstrap resampling is conducted pairwise on (y, X, Z) (i.e., by resampling from rows of the (y, X) data or (y, X, Z) data where appropriate). `inid` admits general heteroskedasticity of unknown form, though it does not allow for dependence. `fixed` conducts Kunsch's (1988) block bootstrap for dependent data, while `geom` conducts Politis and Romano's (1994) stationary bootstrap.

For consistency of the block and stationary bootstrap, the (mean) block length b should grow with the sample size n at an appropriate rate. If b is not given, then a default growth rate of $const \times n^{1/3}$ is used. This rate is "optimal" under certain conditions (see Politis and Romano (1994) for more details). However, in general the growth rate depends on the specific properties of the DGP. A default value for `const` (3.15) has been determined by a Monte Carlo simulation using a Gaussian AR(1) process (AR(1)-parameter of 0.5, 500 observations). `const` has been chosen such that the mean square error for the bootstrap estimate of the variance of the empirical mean is minimized.

Value

Setting `plot.behavior` will instruct `npplot` what data to return. Option summary:

`plot`: instruct `npplot` to just plot the data and return NULL

`plot-data`: instruct `npplot` to plot the data and return the data used to generate the plots. The data will be a list of objects of the appropriate type, with one object per plot. For example, invoking `npplot` on 3D density data will have it return a list of three `npdensity` objects. If biases were calculated, they are stored in a component named `bias`

`data`: instruct `npplot` to generate data only and no plots

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Examples

```
## Not run:
# EXAMPLE 1: For this example, we load Giovanni Baiocchi's Italian GDP
# panel (see Italy for details), then create a data frame in which year
# is an ordered factor, GDP is continuous, compute bandwidths using
# likelihood cross-validation, then create a grid of data on which the
# density will be evaluated for plotting purposes

data("Italy")
attach(Italy)

data <- data.frame(ordered(year), gdp)

# Compute bandwidths using likelihood cross-validation (default). Note
# that this may take a minute or two depending on the speed of your
# computer...

bw <- npudensbw(dat=data)

# You can always do things manually, as the following example demonstrates

# Create an evaluation data matrix

year.seq <- sort(unique(year))
gdp.seq <- seq(1,36,length=50)
data.eval <- expand.grid(year=year.seq,gdp=gdp.seq)

# Generate the estimated density computed for the evaluation data

fhat <- fitted(npudens(tdat = data, edat = data.eval, bws=bw))

# Coerce the data into a matrix for plotting with persp()

f <- matrix(fhat, length(unique(year)), 50)

# Next, create a 3D perspective plot of the PDF f

persp(as.integer(levels(year.seq)), gdp.seq, f, col="lightblue",
      ticktype="detailed", ylab="GDP", xlab="Year", zlab="Density",
      theta=300, phi=50)
```

```
# Sleep for 5 seconds so that we can examine the output...

Sys.sleep(5)

# However, npplot simply streamlines this process and aids in the
# visualization process (<ctrl>-C will interrupt on *NIX systems, <esc>
# will interrupt on MS Windows systems).

plot(bw)

# npplot also streamlines construction of variability bounds (<ctrl>-C
# will interrupt on *NIX systems, <esc> will interrupt on MS Windows
# systems)

plot(bw, plot.errors.method = "asymptotic")

# EXAMPLE 2: For this example, we simulate multivariate data, and plot the
# partial regression surfaces for a locally linear estimator and its
# derivatives.

 npplreg

Partially Linear Kernel Regression with Mixed Data Types

Description

npplreg computes a partially linear kernel regression estimate of a one (1) dimensional dependent variable on $p + q$ -variate explanatory data, using the model $Y = X\beta + \Theta(Z) + \epsilon$ given a set of estimation points, training points (consisting of explanatory data and dependent data), and a bandwidth specification, which can be a rbandwidth object, or a bandwidth vector, bandwidth type and kernel type.

Usage

```
npplreg(bws, ...)
```

S3 method for class 'formula'

```
npplreg(bws, data = NULL, newdata = NULL, y.eval =
FALSE, ...)
```

S3 method for class 'call'

```
npplreg(bws, ...)
```

S3 method for class 'plbandwidth'

```
npplreg(bws,
        txdat = stop("training data txdat missing"),
        tydat = stop("training data tydat missing"),
        tzdat = stop("training data tzdat missing"),
        exdat,
        eydat,
        ezdat,
        residuals = FALSE,
        ...)
```

Arguments

bws	a bandwidth specification. This can be set as a <code>plbandwidth</code> object returned from an invocation of <code>npplregbw</code> , or as a matrix of bandwidths, where each row is a set of bandwidths for Z , with a column for each variable Z_i . In the first row are the bandwidths for the regression of Y on Z , the following rows contain the bandwidths for the regressions of the columns of X on Z . If specified as a matrix additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, training data, and so on.
...	additional arguments supplied to specify the regression type, bandwidth type, kernel types, selection methods, and so on. To do this, you may specify any of <code>regtype</code> , <code>bwmethod</code> , <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> , as described in <code>npregbw</code> .
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in data, the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npplregbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
y.eval	If <code>newdata</code> contains dependent data and <code>y.eval = TRUE</code> , <code>np</code> will compute goodness of fit statistics on these data and return them. Defaults to <code>FALSE</code> .
txdat	a p -variate data frame of explanatory data (training data), corresponding to X in the model equation, whose linear relationship with the dependent data Y is posited. Defaults to the training data used to compute the bandwidth object.
tydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>txdat</code> . Defaults to the training data used to compute the bandwidth object.
tzdat	a q -variate data frame of explanatory data (training data), corresponding to Z in the model equation, whose relationship to the dependent variable is unspecified (nonparametric). Defaults to the training data used to compute the bandwidth object.
exdat	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>txdat</code> .
eydat	a one (1) dimensional numeric or integer vector of the true values of the dependent variable. Optional, and used only to calculate the true errors. By default, evaluation takes place on the data provided by <code>tydat</code> .
ezdat	a q -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>tzdat</code> .
residuals	a logical value indicating that you want residuals computed and returned in the resulting <code>plregression</code> object. Defaults to <code>FALSE</code> .

Details

`npplreg` uses a combination of OLS and nonparametric regression to estimate the parameter β in the model $Y = X\beta + \Theta(Z) + \epsilon$.

npplreg implements a variety of methods for nonparametric regression on multivariate (q -variate) explanatory data defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

Data contained in the data frame `tzdat` may be a mix of continuous (default), unordered discrete (to be specified in the data frame `tzdat` using `factor`), and ordered discrete (to be specified in the data frame `tzdat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

npplreg returns a `plregression` object. The generic accessor functions `coef`, `fitted`, `residuals`, `predict`, and `vcov`, extract (or estimate) coefficients, estimated values, residuals, predictions, and variance-covariance matrices, respectively, from the returned object. Furthermore, the functions `summary` and `plot` support objects of this type. The returned object has the following components:

<code>evalx</code>	evaluation points
<code>evalz</code>	evaluation points
<code>mean</code>	estimation of the regression, or conditional mean, at the evaluation points
<code>xcoef</code>	coefficient(s) corresponding to the components β_i in the model
<code>xcoeferr</code>	standard errors of the coefficients
<code>xcoefvcov</code>	covariance matrix of the coefficients
<code>bw</code>	the bandwidths, stored as a <code>plbandwidth</code> object
<code>resid</code>	if <code>residuals = TRUE</code> , in-sample or out-of-sample residuals where appropriate (or possible)
<code>R2</code>	coefficient of determination (Doksum and Samarov (1995))
<code>MSE</code>	mean squared error
<code>MAE</code>	mean absolute error
<code>MAPE</code>	mean absolute percentage error
<code>CORR</code>	absolute value of Pearson’s correlation coefficient
<code>SIGN</code>	fraction of observations where fitted and observed values agree in sign

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

          zdat = stop("invoked without data `zdat`"),
          bws,
          nmulti,
          ...)

```

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
xdat	a p -variate data frame of explanatory data (training data), corresponding to X in the model equation, whose linear relationship with the dependent data Y is posited.
ydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
zdat	a q -variate data frame of explanatory data (training data), corresponding to Z in the model equation, whose relationship to the dependent variable is unspecified (nonparametric)

bws	a bandwidth specification. This can be set as a plbandwidth object returned from an invocation of npplregbw, or as a matrix of bandwidths, where each row is a set of bandwidths for Z , with a column for each variable Z_i . In the first row are the bandwidths for the regression of Y on Z . The following rows contain the bandwidths for the regressions of the columns of X on Z . If specified as a matrix, additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, and so on. If left unspecified, npplregbw will search for optimal bandwidths using npregbw in the course of calculations. If specified, npplregbw will use the given bandwidths as the starting point for the numerical search for optimal bandwidths, unless you specify bandwidth.compute = FALSE.
...	additional arguments supplied to specify the regression type, bandwidth type, kernel types, selection methods, and so on. To do this, you may specify any of regtype, bwmethod, bwscaling, bwtype, ckertype, ckerorder, ukertype, okertype, as described in npregbw.
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to FALSE, a plbandwidth object will be returned with bandwidths set to those specified in bws. Defaults to TRUE.
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points. Defaults to $\min(5, \text{ncol}(\text{zdat}))$.
remin	a logical value which when set as TRUE the search routine restarts from located minima for a minor gain in accuracy. Defaults to TRUE
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000
ftol	tolerance on the value of the cross-validation function evaluated at located minima. Defaults to $1.19\text{e-}07$ (FLT_EPSILON)
tol	tolerance on the position of located minima of the cross-validation function. Defaults to $1.49\text{e-}08$ (sqrt(DBL_EPSILON))
small	a small number, at about the precision of the data type used. Defaults to $2.22\text{e-}16$ (DBL_EPSILON)

Details

npplregbw implements a variety of methods for nonparametric regression on multivariate (q -variate) explanatory data defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003), who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

npplregbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the xdat, ydat, and zdat parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `zdat` may be a mix of continuous (default), unordered discrete (to be specified in the data frame `zdat` using `factor`), and ordered discrete (to be specified in the data frame `zdat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form dependent data \sim parametric explanatory data | nonparametric explanatory data, where dependent data is a univariate response, and parametric explanatory data and nonparametric explanatory data are both series of variables specified by name, separated by the separation character `'|'`. For example, `y1 ~ x1 + x2 | z1` specifies that the bandwidth object for the partially linear model with response `y1`, linear parametric regressors `x1` and `x2`, and nonparametric regressor `z1` is to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

if `bwtype` is set to `fixed`, an object containing bandwidths (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables. Bandwidths are stored in a list under the component name `bw`. Each element is an `rbandwidth` object. The first element of the list corresponds to the regression of Y on Z . Each subsequent element is the bandwidth object corresponding to the regression of the i th column of X on Z . See examples for more information.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(zdat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

```

npqcmstest

*Kernel Consistent Quantile Regression Model Specification Test with
Mixed Data Types*

Description

npqcmstest implements a consistent test for correct specification of parametric quantile regression models (linear or nonlinear) as described in Racine (2006) which extends the work of Zheng (1998).

Usage

```

npqcmstest(formula,
           data = NULL,
           subset,

```

```
xdat,
ydat,
model = stop(paste(sQuote("model"), " has not been provided")),
tau = 0.5,
distribution = c("bootstrap", "asymptotic"),
bwydat = c("y", "varepsilon"),
boot.method = c("iid", "wild", "wild-rademacher"),
boot.num = 399,
pivot = TRUE,
density.weighted = TRUE,
random.seed = 42,
...)
```

Arguments

formula	a symbolic description of variables on which the test is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from environment(formula), typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used.
model	a model object obtained from a call to rq . Important: the call to rq must have the argument model=TRUE or npqcmstest will not work.
xdat	a p -variate data frame of explanatory data (training data) used to calculate the quantile regression estimators.
ydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of xdat.
tau	a numeric value specifying the τ th quantile is desired
distribution	a character string used to specify the method of estimating the distribution of the statistic to be calculated. bootstrap will conduct bootstrapping. asymptotic will use the normal distribution. Defaults to bootstrap.
bwydat	a character string used to specify the left hand side variable used in bandwidth selection. "varepsilon" uses $1 - \tau$, $-\tau$ for ydat while "y" will use y . Defaults to "y".
boot.method	a character string used to specify the bootstrap method. iid will generate independent identically distributed draws. wild will use a wild bootstrap. wild-rademacher will use a wild bootstrap with Rademacher variables. Defaults to iid.
boot.num	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
pivot	a logical value specifying whether the statistic should be normalised such that it approaches $N(0, 1)$ in distribution. Defaults to TRUE.
density.weighted	a logical value specifying whether the statistic should be weighted by the density of xdat. Defaults to TRUE.

random.seed	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.
...	additional arguments supplied to control bandwidth selection on the residuals. One can specify the bandwidth type, kernel types, and so on. To do this, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> , as described in <code>npregbw</code> . This is necessary if you specify <code>bws</code> as a p -vector and not a bandwidth object, and you do not desire the default behaviours.

Value

`npqcmstest` returns an object of type `cmstest` with the following components. Components will contain information related to J_n or I_n depending on the value of `pivot`:

<code>Jn</code>	the statistic J_n
<code>In</code>	the statistic I_n
<code>Omega.hat</code>	as described in Racine, J.S. (2006).
<code>q.*</code>	the various quantiles of the statistic J_n (or I_n if <code>pivot=FALSE</code>) are in components <code>q.90</code> , <code>q.95</code> , <code>q.99</code> (one-sided 1%, 5%, 10% critical values)
<code>P</code>	the P-value of the statistic
<code>Jn.bootstrap</code>	if <code>pivot=TRUE</code> contains the bootstrap replications of J_n
<code>In.bootstrap</code>	if <code>pivot=FALSE</code> contains the bootstrap replications of I_n

`summary` supports object of type `cmstest`.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

npqreg
```

```
Kernel Quantile Regression with Mixed Data Types
```

Description

npqreg computes a kernel quantile regression estimate of a one (1) dimensional dependent variable on p -variate explanatory data, given a set of evaluation points, training points (consisting of explanatory data and dependent data), and a bandwidth specification using the methods of Li and Racine (2008) and Li, Lin and Racine (2013). A bandwidth specification can be a condbandwidth object, or a bandwidth vector, bandwidth type and kernel type.

Usage

```
npqreg(bws, ...)

## S3 method for class 'formula'
npqreg(bws, data = NULL, newdata = NULL, ...)

## S3 method for class 'call'
npqreg(bws, ...)

## S3 method for class 'condbandwidth'
npqreg(bws,
      txdat = stop("training data 'txdat' missing"),
      tydat = stop("training data 'tydat' missing"),
      exdat,
      tau = 0.5,
      gradients = FALSE,
      ftol = 1.490116e-07,
      tol = 1.490116e-04,
      small = 1.490116e-05,
      itmax = 10000,
      lbc.dir = 0.5,
      dfc.dir = 3,
      cfac.dir = 2.5*(3.0-sqrt(5)),
      initc.dir = 1.0,
      lbd.dir = 0.1,
      hbd.dir = 1,
      dfac.dir = 0.25*(3.0-sqrt(5)),
      initd.dir = 1.0,
      ...)

## Default S3 method:
npqreg(bws, txdat, tydat, ...)
```

Arguments

bws	a bandwidth specification. This can be set as a <code>condbandwidth</code> object returned from an invocation of <code>npcdistbw</code> , or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>txdat</code> . If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, and so on.
tau	a numeric value specifying the τ th quantile is desired. Defaults to 0.5.
...	additional arguments supplied to specify the regression type, bandwidth type, kernel types, training data, and so on. To do this, you may specify any of <code>bwmethod</code> , <code>bwscaling</code> , <code>bwtype</code> , <code>cxkertype</code> , <code>cxkerorder</code> , <code>cykertype</code> , <code>cykerorder</code> , <code>uxkertype</code> , <code>uykertype</code> , <code>oxkertype</code> , <code>oykertype</code> , as described in <code>npcdistbw</code> .
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npcdistbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
txdat	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators. Defaults to the training data used to compute the bandwidth object.
tydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>txdat</code> . Defaults to the training data used to compute the bandwidth object.
exdat	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>txdat</code> .
gradients	[currently not supported] a logical value indicating that you want gradients computed and returned in the resulting <code>npregression</code> object. Defaults to <code>FALSE</code> .
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
ftol	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01*\sqrt{.Machine\$double.eps}$).
tol	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine's floating point precision). Defaults to $1.490116e-04$ ($1.0e+04*\sqrt{.Machine\$double.eps}$).
small	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\sqrt{\text{epsilon}}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision)). Defaults to <code>small = 1.490116e-05</code> ($1.0e+03*\sqrt{.Machine\$double.eps}$).
lbc.dir,dfc.dir,cfac.dir,initc.dir	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
lbd.dir,hbd.dir,dfac.dir,initd.dir	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details

Details

The optimizer invoked for search is Powell’s conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and, when restarting, random values for successive invocations. Bandwidths for numeric variables are scaled by robust measures of spread, the sample size, and the number of numeric variables where appropriate. Two sets of parameters for bandwidths for numeric can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell’s algorithm does not involve explicit computation of the function’s gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable ‘tuning’ for various methods rather than for the user themselves.

Value

`npqreg` returns a `npqregression` object. The generic functions `fitted` (or `quantile`), `se`, `predict` (when using `predict` you must add the argument `tau=` to generate predictions other than the median), and `gradients`, extract (or generate) estimated values, asymptotic standard errors on estimates, predictions, and gradients, respectively, from the returned object. Furthermore, the functions `summary` and `plot` support objects of this type. The returned object has the following components:

<code>eval</code>	evaluation points
<code>quantile</code>	estimation of the quantile regression function (conditional quantile) at the evaluation points
<code>quanterr</code>	standard errors of the quantile regression estimates
<code>quantgrad</code>	gradients at each evaluation point
<code>tau</code>	the τ th quantile computed

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

npquantile

Kernel Univariate Quantile Estimation

Description

npquantile computes smooth quantiles from a univariate kernel unconditional cumulative distribution estimate given data and, optionally, a bandwidth specification i.e. a dbandwidth object using

the bandwidth selection method of Li and Racine (2013).

Usage

```
npquantile(x = NULL,
           tau = c(0.01, 0.05, 0.25, 0.50, 0.75, 0.95, 0.99),
           num.eval = 10000,
           bws = NULL,
           f = 1,
           ...)
```

Arguments

x	a univariate vector of type <code>numeric</code> containing sample realizations (training data) used to estimate the cumulative distribution (must be the same training data used to compute the bandwidth object <code>bws</code> passed in).
tau	an optional vector containing the probabilities for quantile(s) to be estimated (must contain numbers in $[0, 1]$). Defaults to <code>c(0.01, 0.05, 0.25, 0.50, 0.75, 0.95, 0.99)</code> .
num.eval	an optional integer specifying the length of the grid on which the quasi-inverse is computed. Defaults to <code>10000</code> .
bws	an optional <code>dbandwidth</code> specification (if already computed avoid unnecessary computation inside <code>npquantile</code>). This must be set as a <code>dbandwidth</code> object returned from an invocation of <code>npudistbw</code> . If not provided <code>npudistbw</code> is invoked with optional arguments passed via <code>...</code>
f	an optional argument fed to <code>extendrange</code> . Defaults to 1. See <code>?extendrange</code> for details.
...	additional arguments supplied to specify the bandwidth type, kernel types, bandwidth selection methods, and so on. See <code>?npudistbw</code> for details.

Details

Typical usage is

```
x <- rchisq(100, df=10)
npquantile(x)
```

The quantile function q_τ is defined to be the left-continuous inverse of the distribution function $F(x)$, i.e. $q_\tau = \inf\{x : F(x) \geq \tau\}$.

A traditional estimator of q_τ is the τ th sample quantile. However, these estimates suffer from lack of efficiency arising from variability of individual order statistics; see Sheather and Marron (1990) and Hyndman and Fan (1996) for methods that interpolate/smooth the order statistics, each of which discussed in the latter can be invoked through `quantile` via `type=j, j=1, ..., 9`.

The function `npquantile` implements a method for estimating smooth quantiles based on the quasi-inverse of a `npudist` object where $F(x)$ is replaced with its kernel estimator and bandwidth selection is that appropriate for such objects; see Definition 2.3.6, page 21, Nelsen 2006 for a definition of the quasi-inverse of $F(x)$.

For construction of the quasi-inverse we create a grid of evaluation points based on the function `extendrange` along with the sample quantiles themselves computed from invocation of `quantile`. The coarseness of the grid defined by `extendrange` (which has been passed the option `f=1`) is controlled by `num.eval`.

Note that for any value of τ less/greater than the smallest/largest value of $F(x)$ computed for the evaluation data (i.e. that outlined in the paragraph above), the quantile returned for such values is that associated with the smallest/largest value of $F(x)$, respectively.

Value

`npquantile` returns a vector of quantiles corresponding to `tau`.

Usage Issues

Cross-validated bandwidth selection is used by default (`npudistbw`). For large datasets this can be computationally demanding. In such cases one might instead consider a rule-of-thumb bandwidth (`bwmethod="normal-reference"`) or, alternatively, use kd-trees (options(`np.tree=TRUE`) along with a bounded kernel (`ckertype="epanechnikov"`)), both of which will reduce the computational burden appreciably.

Examples

```
## Not run:
## Simulate data from a chi-square distribution
df <- 50
x <- rchisq(100,df=df)

## Vector of quantiles desired
tau <- c(0.01,0.05,0.25,0.50,0.75,0.95,0.99)
```

```

## Compute kernel smoothed sample quantiles
npquantile(x,tau)

## Compute sample quantiles using the default method in R (Type 7)
quantile(x,tau)

## True quantiles based on known distribution
qchisq(tau,df=df)

## End(Not run)

```

npreg

Kernel Regression with Mixed Data Types

Description

npreg computes a kernel regression estimate of a one (1) dimensional dependent variable on p -variate explanatory data, given a set of evaluation points, training points (consisting of explanatory data and dependent data), and a bandwidth specification using the method of Racine and Li (2004) and Li and Racine (2004). A bandwidth specification can be a rbandwidth object, or a bandwidth vector, bandwidth type and kernel type.

Usage

```

npreg(bws, ...)

## S3 method for class 'formula'
npreg(bws, data = NULL, newdata = NULL, y.eval =
FALSE, ...)

## S3 method for class 'call'
npreg(bws, ...)

## Default S3 method:
npreg(bws, txdat, tydat, ...)

## S3 method for class 'rbandwidth'
npreg(bws,
      txdat = stop("training data 'txdat' missing"),
      tydat = stop("training data 'tydat' missing"),
      exdat,
      eydat,
      gradients = FALSE,
      residuals = FALSE,
      ...)

```

Arguments

<code>bws</code>	a bandwidth specification. This can be set as a <code>rbandwidth</code> object returned from an invocation of <code>npregbw</code> , or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>txdat</code> . If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, and so on.
<code>...</code>	additional arguments supplied to specify the regression type, bandwidth type, kernel types, training data, and so on, detailed below.
<code>data</code>	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npregbw</code> was called.
<code>newdata</code>	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
<code>y.eval</code>	If <code>newdata</code> contains dependent data and <code>y.eval = TRUE</code> , <code>np</code> will compute goodness of fit statistics on these data and return them. Defaults to <code>FALSE</code> .
<code>txdat</code>	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators. Defaults to the training data used to compute the bandwidth object.
<code>tydat</code>	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>txdat</code> . Defaults to the training data used to compute the bandwidth object.
<code>exdat</code>	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>txdat</code> .
<code>eydat</code>	a one (1) dimensional numeric or integer vector of the true values of the dependent variable. Optional, and used only to calculate the true errors.
<code>gradients</code>	a logical value indicating that you want gradients computed and returned in the resulting <code>npregression</code> object. Defaults to <code>FALSE</code> .
<code>residuals</code>	a logical value indicating that you want residuals computed and returned in the resulting <code>npregression</code> object. Defaults to <code>FALSE</code> .

Details

Typical usages are (see below for a complete list of options and also the examples at the end of this help file)

Usage 1: first compute the bandwidth object via `npregbw` and then compute the conditional mean:

```
bw <- npregbw(y~x)
ghat <- npreg(bw)
```

Usage 2: alternatively, compute the bandwidth object indirectly:

```
ghat <- npreg(y~x)
```

Usage 3: modify the default kernel and order:

```
ghat <- npreg(y~x, ckertype="epanechnikov", ckerorder=4)
```

Usage 4: use the data frame interface rather than the formula interface:

```
ghat <- npreg(tydat=y, txdat=x, ckertype="epanechnikov", ckerorder=4)
```

npreg implements a variety of methods for regression on multivariate (p -variate) data, the types of which are possibly continuous and/or discrete (unordered, ordered). The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

Data contained in the data frame `txdat` may be a mix of continuous (default), unordered discrete (to be specified in the data frame `txdat` using `factor`), and ordered discrete (to be specified in the data frame `txdat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see [np](#) for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The use of compactly supported kernels or the occurrence of small bandwidths can lead to numerical problems for the local linear estimator when computing the locally weighted least squares solution. To overcome this problem we rely on a form of ‘ridging’ proposed by Cheng, Hall, and Titterington (1997), modified so that we solve the problem pointwise rather than globally (i.e. only when it is needed).

Value

npreg returns a `npregression` object. The generic functions `fitted`, `residuals`, `se`, `predict`, and `gradients`, extract (or generate) estimated values, residuals, asymptotic standard errors on estimates, predictions, and gradients, respectively, from the returned object. Furthermore, the functions `summary` and `plot` support objects of this type. The returned object has the following components:

<code>eval</code>	evaluation points
<code>mean</code>	estimates of the regression function (conditional mean) at the evaluation points
<code>merr</code>	standard errors of the regression function estimates
<code>grad</code>	estimates of the gradients at each evaluation point
<code>gerr</code>	standard errors of the gradient estimates

resid	if residuals = TRUE, in-sample or out-of-sample residuals where appropriate (or possible)
R2	coefficient of determination (Doksum and Samarov (1995))
MSE	mean squared error
MAE	mean absolute error
MAPE	mean absolute percentage error
CORR	absolute value of Pearson's correlation coefficient
SIGN	fraction of observations where fitted and observed values agree in sign

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

npregbw

Kernel Regression Bandwidth Selection with Mixed Data Types

Description

npregbw computes a bandwidth object for a p -variate kernel regression estimator defined over mixed continuous and discrete (unordered, ordered) data using expected Kullback-Leibler cross-validation, or least-squares cross validation using the method of Racine and Li (2004) and Li and Racine (2004).

Usage

```

npregbw(...)

## S3 method for class 'formula'
npregbw(formula, data, subset, na.action, call, ...)

## S3 method for class 'NULL'
npregbw(xdat = stop("invoked without data 'xdat'"),
        ydat = stop("invoked without data 'ydat'"),
        bws,
        ...)

```

```
## Default S3 method:
npregbw(xdat = stop("invoked without data 'xdat'"),
        ydat = stop("invoked without data 'ydat'"),
        bws,
        bandwidth.compute = TRUE,
        nmulti,
        remin,
        itmax,
        ftol,
        tol,
        small,
        lbc.dir,
        dfc.dir,
        cfac.dir,
        initc.dir,
        lbd.dir,
        hbd.dir,
        dfac.dir,
        initd.dir,
        lbc.init,
        hbc.init,
        cfac.init,
        lbd.init,
        hbd.init,
        dfac.init,
        scale.init.categorical.sample,
        regtype,
        bwmethod,
        bwscaling,
        bwtype,
        ckertype,
        ckerorder,
        ukertype,
        okertype,
        ...)

## S3 method for class 'rbandwidth'
npregbw(xdat = stop("invoked without data 'xdat'"),
        ydat = stop("invoked without data 'ydat'"),

```

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
xdat	a p -variate data frame of regressors on which bandwidth selection will be performed. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
ydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
bws	a bandwidth specification. This can be set as a <code>rbandwidth</code> object returned from a previous invocation, or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>xdat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
...	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.

regtype	a character string specifying which type of kernel regression estimator to use. lc specifies a local-constant estimator (Nadaraya-Watson) and ll specifies a local-linear estimator. Defaults to lc.
bwmethod	which method to use to select bandwidths. cv.aic specifies expected Kullback-Leibler cross-validation (Hurvich, Simonoff, and Tsai (1998)), and cv.ls specifies least-squares cross-validation. Defaults to cv.ls.
bwscaling	a logical value that when set to TRUE the supplied bandwidths are interpreted as ‘scale factors’ (c_j), otherwise when the value is FALSE they are interpreted as ‘raw bandwidths’ (h_j for continuous data types, λ_j for discrete data types). For continuous data types, c_j and h_j are related by the formula $h_j = c_j \sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of continuous variable j defined as $\min(\text{standard deviation}, \text{mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(2P+l)}$, where here j denotes discrete variable j . Defaults to FALSE.
bwtype	character string used for the continuous variable bandwidth type, specifying the type of bandwidth to compute and return in the bandwidth object. Defaults to fixed. Option summary: fixed: compute fixed bandwidths generalized_nn: compute generalized nearest neighbors adaptive_nn: compute adaptive nearest neighbors
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to FALSE, a rbandwidth object will be returned with bandwidths set to those specified in bws. Defaults to TRUE.
ckertype	character string used to specify the continuous kernel type. Can be set as gaussian, epanechnikov, or uniform. Defaults to gaussian.
ckerorder	numeric value specifying kernel order (one of (2, 4, 6, 8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
ukertype	character string used to specify the unordered categorical kernel type. Can be set as aitchisonaitken or liracine. Defaults to aitchisonaitken.
okertype	character string used to specify the ordered categorical kernel type. Can be set as wangvanryzin or liracine. Defaults to liracine.
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points. Defaults to $\min(5, \text{ncol}(\text{xdat}))$.
remin	a logical value which when set as TRUE the search routine restarts from located minima for a minor gain in accuracy. Defaults to TRUE.
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
ftol	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01 * \text{sqrt}(.Machine\$double.eps)$).
tol	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine’s floating point precision). Defaults to $1.490116e-04$ ($1.0e+04 * \text{sqrt}(.Machine\$double.eps)$).

<code>small</code>	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\sqrt{\text{epsilon}}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision)). Defaults to <code>small = 1.490116e-05 (1.0e+03*sqrt(.Machine\$double.eps))</code> .
<code>lbc.dir, dfc.dir, cfac.dir, initc.dir</code>	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
<code>lbd.dir, hbd.dir, dfac.dir, initd.dir</code>	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details
<code>lbc.init, hbc.init, cfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for numeric variables for Powell's algorithm. See Details
<code>lbd.init, hbd.init, dfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for categorical variables for Powell's algorithm. See Details
<code>scale.init.categorical.sample</code>	a logical value that when set to TRUE scales <code>lbd.dir</code> , <code>hbd.dir</code> , <code>dfac.dir</code> , and <code>initd.dir</code> by $n^{-2/(2P+l)}$, n the number of observations, P the order of the kernel, and l the number of numeric variables. See Details

Details

`npregbw` implements a variety of methods for choosing bandwidths for multivariate (p -variate) regression data defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003) who employ 'generalized product kernels' that admit a mix of continuous and discrete data types.

The cross-validation methods employ multivariate numerical search algorithms (direction set (Powell's) methods in multidimensions).

Bandwidths can (and will) differ for each variable which is, of course, desirable.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

`npregbw` may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the `xdat` and `ydat` parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `xdat` may be a mix of continuous (default), unordered discrete (to be specified in the data frame `xdat` using `factor`), and ordered discrete (to be specified in the data frame `xdat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see [np](#) for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form `dependent data ~ explanatory data`, where `dependent data` is a univariate

response, and explanatory data is a series of variables specified by name, separated by the separation character '+'. For example, $y1 \sim x1 + x2$ specifies that the bandwidths for the regression of response $y1$ and nonparametric regressors $x1$ and $x2$ are to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The use of compactly supported kernels or the occurrence of small bandwidths during cross-validation can lead to numerical problems for the local linear estimator when computing the locally weighted least squares solution. To overcome this problem we rely on a form of 'ridging' proposed by Cheng, Hall, and Titterton (1997), modified so that we solve the problem pointwise rather than globally (i.e. only when it is needed).

The optimizer invoked for search is Powell's conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and, when restarting, random values for successive invocations. Bandwidths for numeric variables are scaled by robust measures of spread, the sample size, and the number of numeric variables where appropriate. Two sets of parameters for bandwidths for numeric can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell's algorithm does not involve explicit computation of the function's gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable 'tuning' for various methods rather than for the user themselves.

Value

`npregbw` returns a `rbandwidth` object, with the following components:

<code>bw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the data, <code>xdat</code>
<code>fval</code>	objective function value at minimum

if `bwtype` is set to `fixed`, an object containing bandwidths (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables. Bandwidths are stored under the component name `bw`, with each element i corresponding to column i of input data `xdat`.

The functions `predict`, `summary`, and `plot` support objects of this class.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing

an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(xdat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

npregiv

Nonparametric Instrumental Regression

Description

npregiv computes nonparametric estimation of an instrumental regression function φ defined by conditional moment restrictions stemming from a structural econometric model: $E[Y - \varphi(Z, X)|W] = 0$, and involving endogenous variables Y and Z and exogenous variables X and instruments W . The function φ is the solution of an ill-posed inverse problem.

When method="Tikhonov", npregiv uses the approach of Darolles, Fan, Florens and Renault (2011) modified for local polynomial kernel regression of any order (Darolles et al use local constant kernel weighting which corresponds to setting $p=0$; see below for details). When method="Landweber-Fridman", npregiv uses the approach of Horowitz (2011) again using local polynomial kernel regression (Horowitz uses B-spline weighting).

Usage

```
npregiv(y,
        z,
        w,
        x = NULL,
        zeval = NULL,
        xeval = NULL,
        p = 1,
        nmulti = 1,
        random.seed = 42,
        optim.maxattempts = 10,
        optim.method = c("Nelder-Mead", "BFGS", "CG"),
        optim.reltol = sqrt(.Machine$double.eps),
        optim.abstol = .Machine$double.eps,
        optim.maxit = 500,
        alpha = NULL,
        alpha.iter = NULL,
        alpha.min = 1e-10,
        alpha.max = 1e-01,
        alpha.tol = .Machine$double.eps^0.25,
        iterate.Tikhonov = TRUE,
        iterate.Tikhonov.num = 1,
        iterate.max = 1000,
        iterate.diff.tol = 1.0e-08,
        constant = 0.5,
        method = c("Landweber-Fridman", "Tikhonov"),
        penalize.iteration = TRUE,
        smooth.residuals = TRUE,
        start.from = c("Eyz", "EEyz"),
        starting.values = NULL,
        stop.on.increase = TRUE,
        return.weights.phi = FALSE,
        return.weights.phi.deriv.1 = FALSE,
        return.weights.phi.deriv.2 = FALSE,
        bw = NULL,
        ...)
```

Arguments

- | | |
|---|--|
| y | a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of z. |
| z | a p -variate data frame of endogenous regressors. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof. |
| w | a q -variate data frame of instruments. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof. |
| x | an r -variate data frame of exogenous regressors. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof. |

zeval	a p -variate data frame of endogenous regressors on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by z .
xeval	an r -variate data frame of exogenous regressors on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by x .
p	the order of the local polynomial regression (defaults to $p=1$, i.e. local linear).
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points.
random.seed	an integer used to seed R's random number generator. This ensures replicability of the numerical search. Defaults to 42.
optim.method	method used by <code>optim</code> for minimization of the objective function. See <code>?optim</code> for references. Defaults to "Nelder-Mead". the default method is an implementation of that of Nelder and Mead (1965), that uses only function values and is robust but relatively slow. It will work reasonably well for non-differentiable functions. method "BFGS" is a quasi-Newton method (also known as a variable metric algorithm), specifically that published simultaneously in 1970 by Broyden, Fletcher, Goldfarb and Shanno. This uses function values and gradients to build up a picture of the surface to be optimized. method "CG" is a conjugate gradients method based on that by Fletcher and Reeves (1964) (but with the option of Polak-Ribiere or Beale-Sorenson updates). Conjugate gradient methods will generally be more fragile than the BFGS method, but as they do not store a matrix they may be successful in much larger optimization problems.
optim.maxattempts	maximum number of attempts taken trying to achieve successful convergence in <code>optim</code> . Defaults to 100.
optim.abstol	the absolute convergence tolerance used by <code>optim</code> . Only useful for non-negative functions, as a tolerance for reaching zero. Defaults to <code>.Machine\$double.eps</code> .
optim.reltol	relative convergence tolerance used by <code>optim</code> . The algorithm stops if it is unable to reduce the value by a factor of <code>'reltol * (abs(val) + reltol)'</code> at a step. Defaults to <code>sqrt(.Machine\$double.eps)</code> , typically about $1e-8$.
optim.maxit	maximum number of iterations used by <code>optim</code> . Defaults to 500.
alpha	a numeric scalar that, if supplied, is used rather than numerically solving for α , when using <code>method="Tikhonov"</code> .
alpha.iter	a numeric scalar that, if supplied, is used for iterated Tikhonov rather than numerically solving for α , when using <code>method="Tikhonov"</code> .
alpha.min	minimum of search range for α , the Tikhonov regularization parameter, when using <code>method="Tikhonov"</code> .
alpha.max	maximum of search range for α , the Tikhonov regularization parameter, when using <code>method="Tikhonov"</code> .
alpha.tol	the search tolerance for <code>optimize</code> when solving for α , the Tikhonov regularization parameter, when using <code>method="Tikhonov"</code> .

<code>iterate.Tikhonov</code>	a logical value indicating whether to use iterated Tikhonov (one iteration) or not when using <code>method="Tikhonov"</code> .
<code>iterate.Tikhonov.num</code>	an integer indicating the number of iterations to conduct when using <code>method="Tikhonov"</code> .
<code>iterate.max</code>	an integer indicating the maximum number of iterations permitted before termination occurs when using <code>method="Landweber-Fridman"</code> .
<code>iterate.diff.tol</code>	the search tolerance for the difference in the stopping rule from iteration to iteration when using <code>method="Landweber-Fridman"</code> (disable by setting to zero).
<code>constant</code>	the constant to use when using <code>method="Landweber-Fridman"</code> .
<code>method</code>	the regularization method employed (defaults to "Landweber-Fridman", see Horowitz (2011); see Darolles, Fan, Florens and Renault (2011) for details for "Tikhonov").
<code>penalize.iteration</code>	a logical value indicating whether to penalize the norm by the number of iterations or not (default TRUE)
<code>smooth.residuals</code>	a logical value indicating whether to optimize bandwidths for the regression of $(y - \varphi(z))$ on w (defaults to TRUE) or for the regression of $\varphi(z)$ on w during iteration
<code>start.from</code>	a character string indicating whether to start from $E(Y z)$ (default, "Eyz") or from $E(E(Y z) z)$ (this can be overridden by providing <code>starting.values</code> below)
<code>starting.values</code>	a value indicating whether to commence Landweber-Fridman assuming $\varphi_{-1} = \text{starting.values}$ (proper Landweber-Fridman) or instead begin from $E(y z)$ (defaults to NULL, see details below)
<code>stop.on.increase</code>	a logical value (defaults to TRUE) indicating whether to halt iteration if the stopping criterion (see below) increases over the course of one iteration (i.e. it may be above the iteration tolerance but increased)
<code>return.weights.phi</code>	a logical value (defaults to FALSE) indicating whether to return the weight matrix which when postmultiplied by the response y delivers the instrumental regression
<code>return.weights.phi.deriv.1</code>	a logical value (defaults to FALSE) indicating whether to return the weight matrix which when postmultiplied by the response y delivers the first partial derivative of the instrumental regression with respect to z
<code>return.weights.phi.deriv.2</code>	a logical value (defaults to FALSE) indicating whether to return the weight matrix which when postmultiplied by the response y delivers the second partial derivative of the instrumental regression with respect to z
<code>bw</code>	an object which, if provided, contains bandwidths and parameters (obtained from a previous invocation of <code>npreziv</code>) required to re-compute the estimator

without having to re-run cross-validation and/or numerical optimization which is particularly costly in this setting (see details below for an illustration of its use)

... additional arguments supplied to `npksum`.

Details

Tikhonov regularization requires computation of weight matrices of dimension $n \times n$ which can be computationally costly in terms of memory requirements and may be unsuitable for large datasets. Landweber-Fridman will be preferred in such settings as it does not require construction and storage of these weight matrices while it also avoids the need for numerical optimization methods to determine α .

`method="Landweber-Fridman"` uses an optimal stopping rule based upon $\|E(y|w) - E(\varphi_k(z, x)|w)\|^2$. However, if insufficient training is conducted the estimates can be overly noisy. To best guard against this eventuality set `nmulti` to a larger number than the default `nmulti=1` for `npregiv`.

When using `method="Landweber-Fridman"`, iteration will terminate when either the change in the value of $\|(E(y|w) - E(\varphi_k(z, x)|w))/E(y|w)\|^2$ from iteration to iteration is less than `iterate.diff.tol` or we hit `iterate.max` or $\|(E(y|w) - E(\varphi_k(z, x)|w))/E(y|w)\|^2$ stops falling in value and starts rising.

The option `bw=` would be useful, say, when bootstrapping is necessary. Note that when passing `bw`, it must be obtained from a previous invocation of `npregiv`. For instance, if `model.iv` was obtained from an invocation of `npregiv` with `method="Landweber-Fridman"`, then the following needs to be fed to the subsequent invocation of `npregiv`:

```
model.iv <- npregiv(...)

bw <- NULL
bw$bw.E.y.w <- model.iv$bw.E.y.w
bw$bw.E.y.z <- model.iv$bw.E.y.z
bw$bw.resid.w <- model.iv$bw.resid.w
bw$bw.resid.fitted.w.z <- model.iv$bw.resid.fitted.w.z
bw$norm.index <- model.iv$norm.index

foo <- npregiv(...,bw=bw)
```

If, on the other hand `model.iv` was obtained from an invocation of `npregiv` with `method="Tikhonov"`, then the following needs to be fed to the subsequent invocation of `npregiv`:

```
model.iv <- npregiv(...)

bw <- NULL
bw$alpha <- model.iv$alpha
bw$alpha.iter <- model.iv$alpha.iter
bw$bw.E.y.w <- model.iv$bw.E.y.w
```

```

bw$bw.E.E.y.w.z <- model.iv$bw.E.E.y.w.z
bw$bw.E.ph.i.w <- model.iv$bw.E.ph.i.w
bw$bw.E.E.ph.i.w.z <- model.iv$bw.E.E.ph.i.w.z

foo <- npregiv(...,bw=bw)

```

Or, if `model.iv` was obtained from an invocation of `npregiv` with either `method="Landweber-Fridman"` or `method="Tikhonov"`, then the following would also work:

```

model.iv <- npregiv(...)

foo <- npregiv(...,bw=model.iv)

```

When exogenous predictors x (`xeval`) are passed, they are appended to both the endogenous predictors z and the instruments w as additional columns. If this is not desired, one can manually append the exogenous variables to z (or w) prior to passing z (or w), and then they will only appear among the z or w as desired.

Value

`npregiv` returns a list with components `phi`, `phi.mat` and either `alpha` when `method="Tikhonov"` or `norm.index`, `norm.stop` and `convergence` when `method="Landweber-Fridman"`, among others.

In addition, if any of `return.weights.*` are invoked ($*$ =1,2), then `phi.weights` and `phi.deriv.*.weights` return weight matrices for computing the instrumental regression and its partial derivatives. Note that these weights, post multiplied by the response vector y , will deliver the estimates returned in `phi`, `phi.deriv.1`, and `phi.deriv.2` (the latter only being produced when p is 2 or greater). When invoked with evaluation data, similar matrices are returned but named `phi.eval.weights` and `phi.deriv.eval.*.weights`. These weights can be used for constrained estimation, among others.

When `method="Landweber-Fridman"` is invoked, bandwidth objects are returned in `bw.E.y.w` (scalar/vector), `bw.E.y.z` (scalar/vector), and `bw.resid.w` (matrix) and `bw.resid.fitted.w.z`, the latter matrices containing bandwidths for each iteration stored as rows. When `method="Tikhonov"` is invoked, bandwidth objects are returned in `bw.E.y.w`, `bw.E.E.y.w.z`, and `bw.E.ph.i.w` and `bw.E.E.ph.i.w.z`.

Note

This function should be considered to be in ‘beta test’ status until further notice.

 npregivderiv

Nonparametric Instrumental Derivatives

Description

npregivderiv uses the approach of Florens and Racine (2012) to compute the partial derivative of a nonparametric estimation of an instrumental regression function φ defined by conditional moment restrictions stemming from a structural econometric model: $E[Y - \varphi(Z, X)|W] = 0$, and involving endogenous variables Y and Z and exogenous variables X and instruments W . The derivative function φ' is the solution of an ill-posed inverse problem, and is computed using Landweber-Fridman regularization.

Usage

```

npregivderiv(y,
             z,
             w,
             x = NULL,
             zeval = NULL,
             weval = NULL,
             xeval = NULL,
             p = 1,
             nmulti = 1,
             random.seed = 42,
             optim.maxattempts = 10,
             optim.method = c("Nelder-Mead", "BFGS", "CG"),
             optim.reltol = sqrt(.Machine$double.eps),
             optim.abstol = .Machine$double.eps,
             optim.maxit = 500,
             iterate.max = 1000,
             iterate.diff.tol = 1.0e-08,

```

```

constant = 0.5,
penalize.iteration = TRUE,
start.from = c("Eyz", "EEyz"),
starting.values = NULL,
stop.on.increase = TRUE,
smooth.residuals = TRUE,
...)
```

Arguments

y	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of z.
z	a p -variate data frame of endogenous regressors. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
w	a q -variate data frame of instruments. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
x	an r -variate data frame of exogenous regressors. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
zeval	a p -variate data frame of endogenous regressors on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by z.
weval	a q -variate data frame of instruments on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by w.
xeval	an r -variate data frame of exogenous regressors on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by x.
p	the order of the local polynomial regression (defaults to $p=1$, i.e. local linear).
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points.
random.seed	an integer used to seed R's random number generator. This ensures replicability of the numerical search. Defaults to 42.
optim.method	method used by <code>optim</code> for minimization of the objective function. See <code>?optim</code> for references. Defaults to "Nelder-Mead". <p>the default method is an implementation of that of Nelder and Mead (1965), that uses only function values and is robust but relatively slow. It will work reasonably well for non-differentiable functions.</p> <p>method "BFGS" is a quasi-Newton method (also known as a variable metric algorithm), specifically that published simultaneously in 1970 by Broyden, Fletcher, Goldfarb and Shanno. This uses function values and gradients to build up a picture of the surface to be optimized.</p> <p>method "CG" is a conjugate gradients method based on that by Fletcher and Reeves (1964) (but with the option of Polak-Ribiere or Beale-Sorenson updates). Conjugate gradient methods will generally be more fragile than the BFGS method, but as they do not store a matrix they may be successful in much larger optimization problems.</p>

<code>optim.maxattempts</code>	maximum number of attempts taken trying to achieve successful convergence in <code>optim</code> . Defaults to 100.
<code>optim.abstol</code>	the absolute convergence tolerance used by <code>optim</code> . Only useful for non-negative functions, as a tolerance for reaching zero. Defaults to <code>.Machine\$double.eps</code> .
<code>optim.reltol</code>	relative convergence tolerance used by <code>optim</code> . The algorithm stops if it is unable to reduce the value by a factor of <code>'reltol * (abs(val) + reltol)'</code> at a step. Defaults to <code>sqrt(.Machine\$double.eps)</code> , typically about $1e-8$.
<code>optim.maxit</code>	maximum number of iterations used by <code>optim</code> . Defaults to 500.
<code>iterate.max</code>	an integer indicating the maximum number of iterations permitted before termination occurs for Landweber-Fridman iteration.
<code>iterate.diff.tol</code>	the search tolerance for the difference in the stopping rule from iteration to iteration when using Landweber-Fridman iteration (disable by setting to zero).
<code>constant</code>	the constant to use for Landweber-Fridman iteration.
<code>penalize.iteration</code>	a logical value indicating whether to penalize the norm by the number of iterations or not (default TRUE)
<code>start.from</code>	a character string indicating whether to start from $E(Y z)$ (default, "Eyz") or from $E(E(Y z) z)$ (this can be overridden by providing <code>starting.values</code> below)
<code>starting.values</code>	a value indicating whether to commence Landweber-Fridman assuming $\varphi'_{-1} = \text{starting.values}$ (proper Landweber-Fridman) or instead begin from $E(y z)$ (defaults to NULL, see details below)
<code>stop.on.increase</code>	a logical value (defaults to TRUE) indicating whether to halt iteration if the stopping criterion (see below) increases over the course of one iteration (i.e. it may be above the iteration tolerance but increased).
<code>smooth.residuals</code>	a logical value (defaults to TRUE) indicating whether to optimize bandwidths for the regression of $y - \varphi(z)$ on w or for the regression of $\varphi(z)$ on w during Landweber-Fridman iteration.
<code>...</code>	additional arguments supplied to <code>npksum</code> .

Details

Note that Landweber-Fridman iteration presumes that $\varphi_{-1} = 0$, and so for derivative estimation we commence iterating from a model having derivatives all equal to zero. Given this starting point it may require a fairly large number of iterations in order to converge. Other perhaps more reasonable starting values might present themselves. When `start.phi.zero` is set to FALSE iteration will commence instead using derivatives from the conditional mean model $E(y|z)$. Should the default iteration terminate quickly or you are concerned about your results, it would be prudent to verify that this alternative starting value produces the same result. Also, check the `norm.stop` vector for any anomalies (such as the error criterion increasing immediately).

Landweber-Fridman iteration uses an optimal stopping rule based upon $\|E(y|w) - E(\varphi_k(z, x)|w)\|^2$. However, if insufficient training is conducted the estimates can be overly noisy. To best guard against this eventuality set `nmulti` to a larger number than the default `nmulti=1` for `npreg`.

Iteration will terminate when either the change in the value of $\|(E(y|w) - E(\varphi_k(z, x)|w))/E(y|w)\|^2$ from iteration to iteration is less than `iterate.diff.tol` or we hit `iterate.max` or $\|(E(y|w) - E(\varphi_k(z, x)|w))/E(y|w)\|^2$ stops falling in value and starts rising.

Value

`npregivderiv` returns a list with components `phi.prime`, `phi`, `num.iterations`, `norm.stop` and `convergence`.

Note

This function currently supports univariate `z` only. This function should be considered to be in 'beta test' status until further notice.

npscoef

Smooth Coefficient Kernel Regression

Description

npscoef computes a kernel regression estimate of a one (1) dimensional dependent variable on p -variate explanatory data, using the model $Y_i = W_i' \gamma(Z_i) + u_i$ where $W_i' = (1, X_i')$, given a set of evaluation points, training points (consisting of explanatory data and dependent data), and a bandwidth specification. A bandwidth specification can be a scbandwidth object, or a bandwidth vector, bandwidth type and kernel type.

Usage

```

npscoef(bws, ...)

## S3 method for class 'formula'
npscoef(bws, data = NULL, newdata = NULL, y.eval =
FALSE, ...)

## S3 method for class 'call'
npscoef(bws, ...)

## Default S3 method:
npscoef(bws, txdat, tydat, tzdat, ...)

## S3 method for class 'scbandwidth'
npscoef(bws,

```

```

txdat = stop("training data 'txdat' missing"),
tydat = stop("training data 'tydat' missing"),
tzdat = NULL,
exdat,
eydat,
ezdat,
residuals = FALSE,
errors = TRUE,
iterate = TRUE,
maxiter = 100,
tol = .Machine$double.eps,
leave.one.out = FALSE,
betas = FALSE,
...)
```

Arguments

bws	a bandwidth specification. This can be set as a <code>scbandwidth</code> object returned from an invocation of <code>npscoefbw</code> , or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>tzdat</code> . If specified as a vector additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, training data, and so on.
...	additional arguments supplied to specify the regression type, bandwidth type, kernel types, selection methods, and so on. To do this, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , as described in <code>npscoefbw</code> .
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npscoefbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.
y.eval	If <code>newdata</code> contains dependent data and <code>y.eval = TRUE</code> , <code>np</code> will compute goodness of fit statistics on these data and return them. Defaults to <code>FALSE</code> .
txdat	a p -variate data frame of explanatory data (training data), which, by default, populates the columns 2 through $p + 1$ of W in the model equation, and in the absence of <code>zdat</code> , will also correspond to Z from the model equation. Defaults to the training data used to compute the bandwidth object.
tydat	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>txdat</code> . Defaults to the training data used to compute the bandwidth object.
tzdat	an optionally specified q -variate data frame of explanatory data (training data), which corresponds to Z in the model equation. Defaults to the training data used to compute the bandwidth object.
exdat	a p -variate data frame of points on which the regression will be estimated (evaluation data). By default, evaluation takes place on the data provided by <code>txdat</code> .
eydat	a one (1) dimensional numeric or integer vector of the true values of the dependent variable. Optional, and used only to calculate the true errors.

ezdat	an optionally specified q -variate data frame of points on which the regression will be estimated (evaluation data), which corresponds to Z in the model equation. Defaults to be the same as txdat.
errors	a logical value indicating whether or not asymptotic standard errors should be computed and returned in the resulting smoothcoefficient object. Defaults to TRUE.
residuals	a logical value indicating that you want residuals computed and returned in the resulting smoothcoefficient object. Defaults to FALSE.
iterate	a logical value indicating whether or not backfitted estimates should be iterated for self-consistency. Defaults to TRUE.
maxiter	integer specifying the maximum number of times to iterate the backfitted estimates while attempting to make the backfitted estimates converge to the desired tolerance. Defaults to 100.
tol	desired tolerance on the relative convergence of backfit estimates. Defaults to <code>.Machine\$double.eps</code> .
leave.one.out	a logical value to specify whether or not to compute the leave one out estimates. Will not work if <code>e[xyz]dat</code> is specified. Defaults to FALSE.
betas	a logical value indicating whether or not estimates of the components of γ should be returned in the smoothcoefficient object along with the regression estimates. Defaults to FALSE.

Value

npscoef returns a smoothcoefficient object. The generic functions `fitted`, `residuals`, `coef`, `se`, and `predict`, extract (or generate) estimated values, residuals, coefficients, bootstrapped standard errors on estimates, and predictions, respectively, from the returned object. Furthermore, the functions `summary` and `plot` support objects of this type. The returned object has the following components:

eval	evaluation points
mean	estimation of the regression function (conditional mean) at the evaluation points
merr	if <code>errors = TRUE</code> , standard errors of the regression estimates
beta	if <code>betas = TRUE</code> , estimates of the coefficients γ at the evaluation points
resid	if <code>residuals = TRUE</code> , in-sample or out-of-sample residuals where appropriate (or possible)
R2	coefficient of determination (Doksum and Samarov (1995))
MSE	mean squared error
MAE	mean absolute error
MAPE	mean absolute percentage error
CORR	absolute value of Pearson's correlation coefficient
SIGN	fraction of observations where fitted and observed values agree in sign

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Support for backfitted bandwidths is experimental and is limited in functionality. The code does not support asymptotic standard errors or out of sample estimates with backfitting.

npscoefbw

Smooth Coefficient Kernel Regression Bandwidth Selection

Description

npscoefbw computes a bandwidth object for a smooth coefficient kernel regression estimate of a one (1) dimensional dependent variable on $p + q$ -variate explanatory data, using the model $Y_i = W_i' \gamma(Z_i) + u_i$ where $W_i' = (1, X_i')$ given training points (consisting of explanatory data and dependent data), and a bandwidth specification, which can be a rbandwidth object, or a bandwidth vector, bandwidth type and kernel type.

Usage

```
npscoefbw(...)
```

S3 method for class 'formula'

```
npscoefbw(formula, data, subset, na.action, call, ...)
```

S3 method for class 'NULL'

```
npscoefbw(xdat = stop("invoked without data 'xdat'"),
          ydat = stop("invoked without data 'ydat'"),

          nmulti,
          random.seed = 42,
          cv.iterate = FALSE,
          cv.num.iterations = 1,
          backfit.iterate = FALSE,
          backfit.maxiter = 100,
          backfit.tol = .Machine$double.eps,
          bandwidth.compute = TRUE,
          optim.method = c("Nelder-Mead", "BFGS", "CG"),
          optim.maxattempts = 10,
          optim.reltol = sqrt(.Machine$double.eps),
          optim.abstol = .Machine$double.eps,
          optim.maxit = 500,
          ...)

```

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The

	default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
<code>call</code>	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
<code>xdat</code>	a p -variate data frame of explanatory data (training data), which, by default, populates the columns 2 through $p + 1$ of W in the model equation, and in the absence of <code>zdat</code> , will also correspond to Z from the model equation.
<code>ydat</code>	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
<code>zdat</code>	an optionally specified q -variate data frame of explanatory data (training data), which corresponds to Z in the model equation. Defaults to be the same as <code>xdat</code> .
<code>bws</code>	a bandwidth specification. This can be set as a <code>scbandwidth</code> object returned from a previous invocation, or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>xdat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
<code>...</code>	additional arguments supplied to specify the regression type, bandwidth type, kernel types, selection methods, and so on, detailed below.
<code>bandwidth.compute</code>	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to <code>FALSE</code> , a <code>scbandwidth</code> object will be returned with bandwidths set to those specified in <code>bws</code> . Defaults to <code>TRUE</code> .
<code>bwmethod</code>	which method was used to select bandwidths. <code>cv.ls</code> specifies least-squares cross-validation, which is all that is currently supported. Defaults to <code>cv.ls</code> .
<code>bwscaling</code>	a logical value that when set to <code>TRUE</code> the supplied bandwidths are interpreted as 'scale factors' (c_j), otherwise when the value is <code>FALSE</code> they are interpreted as 'raw bandwidths' (h_j for continuous data types, λ_j for discrete data types). For continuous data types, c_j and h_j are related by the formula $h_j = c_j \sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of continuous variable j defined as $\min(\text{standard deviation, mean absolute deviation, interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(2P+l)}$, where here j denotes discrete variable j . Defaults to <code>FALSE</code> .
<code>bwtype</code>	character string used for the continuous variable bandwidth type, specifying the type of bandwidth provided. Defaults to <code>fixed</code> . Option summary: <code>fixed</code> : fixed bandwidths or scale factors <code>generalized_nn</code> : generalized nearest neighbors <code>adaptive_nn</code> : adaptive nearest neighbors
<code>ckertype</code>	character string used to specify the continuous kernel type. Can be set as <code>gaussian</code> , <code>epanechnikov</code> , or <code>uniform</code> . Defaults to <code>gaussian</code> .
<code>ckerorder</code>	numeric value specifying kernel order (one of (2, 4, 6, 8)). Kernel order specified along with a <code>uniform</code> continuous kernel type will be ignored. Defaults to 2.

ukertype	character string used to specify the unordered categorical kernel type. Can be set as aitchisonaitken or liracine. Defaults to aitchisonaitken.
okertype	character string used to specify the ordered categorical kernel type. Can be set as wangvanryzin or liracine. Defaults to liracine.
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points. Defaults to $\min(5, \text{ncol}(\text{xdat}))$.
random.seed	an integer used to seed R's random number generator. This ensures replicability of the numerical search. Defaults to 42.
optim.method	method used by <code>optim</code> for minimization of the objective function. See <code>?optim</code> for references. Defaults to "Nelder-Mead". the default method is an implementation of that of Nelder and Mead (1965), that uses only function values and is robust but relatively slow. It will work reasonably well for non-differentiable functions. method "BFGS" is a quasi-Newton method (also known as a variable metric algorithm), specifically that published simultaneously in 1970 by Broyden, Fletcher, Goldfarb and Shanno. This uses function values and gradients to build up a picture of the surface to be optimized. method "CG" is a conjugate gradients method based on that by Fletcher and Reeves (1964) (but with the option of Polak-Ribiere or Beale-Sorenson updates). Conjugate gradient methods will generally be more fragile than the BFGS method, but as they do not store a matrix they may be successful in much larger optimization problems.
optim.maxattempts	maximum number of attempts taken trying to achieve successful convergence in <code>optim</code> . Defaults to 100.
optim.abstol	the absolute convergence tolerance used by <code>optim</code> . Only useful for non-negative functions, as a tolerance for reaching zero. Defaults to <code>.Machine\$double.eps</code> .
optim.reltol	relative convergence tolerance used by <code>optim</code> . The algorithm stops if it is unable to reduce the value by a factor of $'\text{reltol} * (\text{abs}(\text{val}) + \text{reltol})'$ at a step. Defaults to $\sqrt{\text{.Machine$double.eps}}$, typically about $1e-8$.
optim.maxit	maximum number of iterations used by <code>optim</code> . Defaults to 500.
cv.iterate	boolean value specifying whether or not to perform iterative, cross-validated backfitting on the data. See details for limitations of the backfitting procedure. Defaults to FALSE.
cv.num.iterations	integer specifying the number of times to iterate the backfitting process over all covariates. Defaults to 1.
backfit.iterate	boolean value specifying whether or not to iterate evaluations of the smooth coefficient estimator, for extra accuracy, during the cross-validated backfitting procedure. Defaults to FALSE.
backfit.maxiter	integer specifying the maximum number of times to iterate the evaluation of the smooth coefficient estimator in the attempt to obtain the desired accuracy. Defaults to 100.
backfit.tol	tolerance to determine convergence of iterated evaluations of the smooth coefficient estimator. Defaults to <code>.Machine\$double.eps</code> .

Details

npscoefbw implements a variety of methods for semiparametric regression on multivariate ($p + q$ -variate) explanatory data defined over a set of possibly continuous data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

npscoefbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the `xdat`, `ydat`, and `zdat` parameters. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `xdat` may be continuous and in `zdat` may be of mixed type. Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see [np](#) for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form dependent data \sim parametric explanatory data | nonparametric explanatory data, where dependent data is a univariate response, and parametric explanatory data and nonparametric explanatory data are both series of variables specified by name, separated by the separation character ‘+’. For example, `y1 ~ x1 + x2 | z1` specifies that the bandwidth object for the smooth coefficient model with response `y1`, linear parametric regressors `x1` and `x2`, and nonparametric regressor (that is, the slope-changing variable) `z1` is to be estimated. See below for further examples. In the case where the nonparametric (slope-changing) variable is not specified, it is assumed to be the same as the parametric variable.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

if `bwtype` is set to `fixed`, an object containing bandwidths (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables. Bandwidths are stored in a vector under the component name `bw`. Backfitted bandwidths are stored under the component name `bw.fitted`.

The functions [predict](#), [summary](#), and [plot](#) support objects of this class.

Usage Issues

If you are using data of mixed types, then it is advisable to use the [data.frame](#) function to construct your input data and not [cbind](#), since [cbind](#) will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `optim.reltol=.1` and conduct multistarting (the default is to restart `min(5,ncol(zdat))` times). Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

Support for backfitted bandwidths is experimental and is limited in functionality. The code does not support asymptotic standard errors or out of sample estimates with backfitting.

npsdeptest

Kernel Consistent Serial Dependence Test for Univariate Nonlinear Processes

Description

npsdeptest implements the consistent metric entropy test of nonlinear serial dependence as described in Granger, Maasoumi and Racine (2004).

Usage

```

npsdeptest(data = NULL,
            lag.num = 1,
            method = c("integration", "summation"),
            bootstrap = TRUE,
            boot.num = 399,
            random.seed = 42)

```

Arguments

data	a vector containing the variable that can be of type <code>numeric</code> or <code>ts</code> .
lag.num	an integer value specifying the maximum number of lags to use. Defaults to 1.
method	a character string used to specify whether to compute the integral version or the summation version of the statistic. Can be set as <code>integration</code> or <code>summation</code> (see below for details). Defaults to <code>integration</code> .

bootstrap	a logical value which specifies whether to conduct the bootstrap test or not. If set to FALSE, only the statistic will be computed. Defaults to TRUE.
boot.num	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
random.seed	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.

Details

npsdeptest computes the nonparametric metric entropy (normalized Hellinger of Granger, Maaoumi and Racine (2004)) for testing for nonlinear serial dependence, $D[f(y_t, \hat{y}_{t-k}), f(y_t) \times f(\hat{y}_{t-k})]$. Default bandwidths are of the Kullback-Leibler variety obtained via likelihood cross-validation.

The test may be applied to a raw data series or to residuals of user estimated models.

The summation version of this statistic may be numerically unstable when data is sparse (the summation version involves division of densities while the integration version involves differences). Warning messages are produced should this occur ('integration recommended') and should be heeded.

Value

npsdeptest returns an object of type deptest with the following components

Srho	the statistic vector Srho
Srho.cumulant	the cumulant statistic vector Srho.cumulant
Srho.bootstrap.mat	contains the bootstrap replications of Srho
Srho.cumulant.bootstrap.mat	contains the bootstrap replications of Srho.cumulant
P	the P-value vector of the Srho statistic vector
P.cumulant	the P-value vector of the cumulant Srho statistic vector
bootstrap	a logical value indicating whether bootstrapping was performed
boot.num	number of bootstrap replications
lag.num	the number of lags
bw.y	the numeric vector of bandwidths for data marginal density at lag num.lag
bw.y.lag	the numeric vector of bandwidths for lagged data marginal density at lag num.lag
bw.joint	the numeric matrix of bandwidths for data and lagged data joint density at lag num.lag

[summary](#) supports object of type deptest.

Usage Issues

The integration version of the statistic uses multidimensional numerical methods from the [cubature](#) package. See [adaptIntegrate](#) for details. The integration version of the statistic will be substantially slower than the summation version, however, it will likely be both more accurate and powerful.

npseed

Set Random Seed

Description

npseed is a function which sets the random seed in the [np](#) C backend, resetting the random number generator.

Usage

```
npseed(seed)
```

Arguments

seed an integer seed for the random number generator.

Details

npseed provides an interface for setting the random seed (and resetting the random number generator) used by [np](#). The random number generator is used during the bandwidth search procedure to set the search starting point, and in subsequent searches when using multistarting, to avoid being trapped in local minima if the objective function is not globally concave.

Calling npseed will only affect the numerical search if it is performed by the C backend. The affected functions include: [npudensbw](#), [npcdensbw](#), [npregbw](#), [npplregbw](#), [npqreg](#), [npcmstest](#) (via [npregbw](#)), [npqcmstest](#) (via [npregbw](#)), [npsigtest](#) (via [npregbw](#)).

Value

None.

Note

This method currently only supports objects from the [np](#) library.

npsigtest

Kernel Regression Significance Test with Mixed Data Types

Description

npsigtest implements a consistent test of significance of an explanatory variable(s) in a nonparametric regression setting that is analogous to a simple t -test (F -test) in a parametric regression setting. The test is based on Racine, Hart, and Li (2006) and Racine (1997).

Usage

```

npsigtest(bws, ...)

## S3 method for class 'formula'
npsigtest(bws, data = NULL, ...)

## S3 method for class 'call'
npsigtest(bws, ...)

## S3 method for class 'npregression'
npsigtest(bws, ...)

## Default S3 method:
npsigtest(bws, xdat, ydat, ...)

## S3 method for class 'rbandwidth'
npsigtest(bws,
  xdat = stop("data xdat missing"),
  ydat = stop("data ydat missing"),
  boot.num = 399,
  boot.method = c("iid", "wild", "wild-rademacher", "pairwise"),
  boot.type = c("I", "II"),
  pivot=TRUE,
  joint=FALSE,
  index = seq(1, ncol(xdat)),
  random.seed = 42,
  ...)

```

Arguments

<code>bws</code>	a bandwidth specification. This can be set as a <code>rbandwidth</code> object returned from a previous invocation, or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>xdat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths when using <code>boot.type="II"</code> . If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on.
<code>data</code>	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in <code>data</code> , the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npregbw</code> was called.
<code>xdat</code>	a p -variate data frame of explanatory data (training data) used to calculate the regression estimators.
<code>ydat</code>	a one (1) dimensional numeric or integer vector of dependent data, each element i corresponding to each observation (row) i of <code>xdat</code> .
<code>boot.method</code>	a character string used to specify the bootstrap method for determining the null distribution. <code>pairwise</code> resamples pairwise, while the remaining methods use a residual bootstrap procedure. <code>iid</code> will generate independent identically distributed draws. <code>wild</code> will use a wild bootstrap. <code>wild-rademacher</code> will use a wild bootstrap with Rademacher variables. Defaults to <code>iid</code> .
<code>boot.num</code>	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
<code>boot.type</code>	a character string specifying whether to use a ‘Bootstrap I’ or ‘Bootstrap II’ method (see Racine, Hart, and Li (2006) for details). The ‘Bootstrap II’ method re-runs cross-validation for each bootstrap replication and uses the new cross-validated bandwidth for variable i and the original ones for the remaining variables. Defaults to <code>boot.type="I"</code> .
<code>pivot</code>	a logical value which specifies whether to bootstrap a pivotal statistic or not (pivoting is achieved by dividing gradient estimates by their asymptotic standard errors). Defaults to <code>TRUE</code> .
<code>joint</code>	a logical value which specifies whether to conduct a joint test or individual test. This is to be used in conjunction with <code>index</code> where <code>index</code> contains two or more integers corresponding to the variables being tested, where the integers correspond to the variables in the order in which they appear among the set of explanatory variables in the function call to <code>npreg/npregbw</code> . Defaults to <code>FALSE</code> .
<code>index</code>	a vector of indices for the columns of <code>xdat</code> for which the test of significance is to be conducted. Defaults to $(1, 2, \dots, p)$ where p is the number of columns in <code>xdat</code> .
<code>random.seed</code>	an integer used to seed R’s random number generator. This is to ensure replicability. Defaults to 42.
<code>...</code>	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.

Details

npsigtest implements a variety of methods for computing the null distribution of the test statistic and allows the user to investigate the impact of a variety of default settings including whether or not to pivot the statistic (`pivot`), whether pairwise or residual resampling is to be used (`boot.method`), and whether or not to recompute the bandwidths for the variables being tested (`boot.type`), among others.

Defaults are chosen so as to provide reasonable behaviour in a broad range of settings and this involves a trade-off between computational expense and finite-sample performance. However, the default `boot.type="I"`, though computationally expedient, can deliver a test that can be slightly over-sized in small sample settings (e.g. at the 5% level the test might reject 8% of the time for samples of size $n = 100$ for some data generating processes). If the default setting (`boot.type="I"`) delivers a P-value that is in the neighborhood (i.e. slightly smaller) of any classical level (e.g. 0.05) and you only have a modest amount of data, it might be prudent to re-run the test using the more computationally intensive `boot.type="II"` setting to confirm the original result. Note also that `boot.method="pairwise"` is not recommended for the multivariate local linear estimator due to substantial size distortions that may arise in certain cases.

Value

npsigtest returns an object of type `sigtest`. [summary](#) supports `sigtest` objects. It has the following components:

In	the vector of statistics In
P	the vector of P-values for each statistic in In
In.bootstrap	contains a matrix of the bootstrap replications of the vector In, each column corresponding to replications associated with explanatory variables in <code>xdat</code> indexed by <code>index</code> (e.g., if you selected <code>index = c(1,4)</code> then <code>In.bootstrap</code> will have two columns, the first being the bootstrap replications of In associated with variable 1, the second with variable 4).

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: bootstrap methods are, by their nature, *computationally intensive*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default number of bootstrap replications, say, setting them to `boot.num=99`. A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

## End(Not run)

```

npsymtest

Kernel Consistent Density Asymmetry Test with Mixed Data Types

Description

npsymtest implements the consistent metric entropy test of asymmetry as described in Maasoumi and Racine (2009).

Usage

```

npsymtest(data = NULL,
           method = c("integration", "summation"),
           boot.num = 399,
           bw = NULL,
           boot.method = c("iid", "geom"),

```

```
random.seed = 42,
...)
```

Arguments

<code>data</code>	a vector containing the variable.
<code>method</code>	a character string used to specify whether to compute the integral version or the summation version of the statistic. Can be set as <code>integration</code> or <code>summation</code> (see below for details). Defaults to <code>integration</code> .
<code>boot.num</code>	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
<code>bw</code>	a numeric (scalar) bandwidth. Defaults to plug-in (see details below).
<code>boot.method</code>	a character string used to specify the bootstrap method. Can be set as <code>iid</code> or <code>geom</code> (see below for details). Defaults to <code>iid</code> .
<code>random.seed</code>	an integer used to seed R's random number generator. This is to ensure replicability. Defaults to 42.
<code>...</code>	additional arguments supplied to specify the bandwidth type, kernel types, and so on. This is used since we specify <code>bw</code> as a numeric scalar and not a bandwidth object, and is of interest if you do not desire the default behaviours. To change the defaults, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> .

Details

`npsymtest` computes the nonparametric metric entropy (normalized Hellinger of Granger, Maasoumi and Racine (2004)) for testing symmetry using the densities/probabilities of the data and the rotated data, $D[f(y), f(\tilde{y})]$. See Maasoumi and Racine (2009) for details. Default bandwidths are of the plug-in variety (`bw.SJ` for continuous variables and direct plug-in for discrete variables).

For bootstrapping the null distribution of the statistic, `iid` conducts simple random resampling, while `geom` conducts Politis and Romano's (1994) stationary bootstrap using automatic block length selection via the `b.star` function in the `np` package. See the `boot` package for details.

The summation version of this statistic may be numerically unstable when `y` is sparse (the summation version involves division of densities while the integration version involves differences). Warning messages are produced should this occur ('integration recommended') and should be heeded.

Value

`npsymtest` returns an object of type `symtest` with the following components

<code>Srho</code>	the statistic <code>Srho</code>
<code>Srho.bootstrap</code>	contains the bootstrap replications of <code>Srho</code>
<code>P</code>	the P-value of the statistic
<code>boot.num</code>	number of bootstrap replications
<code>data.rotate</code>	the rotated data series
<code>bw</code>	the numeric (scalar) bandwidth

`summary` supports object of type `symtest`.

Usage Issues

When using data of type `factor` it is crucial that the variable not be an alphabetic character string (i.e. the factor must be integer-valued). The rotation is conducted about the median after conversion to type `numeric` which is then converted back to type `factor`. Failure to do so will have unpredictable results. See the example below for proper usage.

nptgauss

Truncated Second-order Gaussian Kernels

Description

nptgauss provides an interface for setting the truncation radius of the truncated second-order Gaussian kernel used by **np**.

Usage

```
nptgauss(b)
```

Arguments

b Truncation radius of the kernel.

Details

nptgauss allows one to set the truncation radius of the truncated Gaussian kernel used by **np**, which defaults to 3. It automatically computes the constants describing the truncated gaussian kernel for the user.

We define the truncated gaussian kernel on the interval $[-b, b]$ as:

$$K = \frac{\alpha}{\sqrt{2\pi}} \left(e^{-z^2/2} - e^{-b^2/2} \right)$$

The constant α is computed as:

$$\alpha = \left[\int_{-b}^b \frac{1}{\sqrt{2\pi}} \left(e^{-z^2/2} - e^{-b^2/2} \right) \right]^{-1}$$

Given these definitions, the derivative kernel is simply:

$$K' = (-z) \frac{\alpha}{\sqrt{2\pi}} e^{-z^2/2}$$

The CDF kernel is:

$$G = \frac{\alpha}{2} \operatorname{erf}(z/\sqrt{2}) + \frac{1}{2} - c_0 z$$

The convolution kernel on $[-2b, 0]$ has the general form:

$$H_- = a_0 \operatorname{erf}(z/2 + b) e^{-z^2/4} + a_1 z + a_2 \operatorname{erf}((z + b)/\sqrt{2}) - c_0$$

and on $[0, 2b]$ it is:

$$H_+ = -a_0 \operatorname{erf}(z/2 - b) e^{-z^2/4} - a_1 z - a_2 \operatorname{erf}((z - b)/\sqrt{2}) - c_0$$

where a_0 is determined by the normalisation condition on H , a_2 is determined by considering the value of the kernel at $z = 0$ and a_1 is determined by the requirement that $H = 0$ at $[-2b, 2b]$.

Examples

```
## The default kernel, a gaussian truncated at +- 3
nptgauss(b = 3.0)
```

Description

npudens computes kernel unconditional density estimates on evaluation data, given a set of training data and a bandwidth specification (a bandwidth object or a bandwidth vector, bandwidth type, and kernel type) using the method of Li and Racine (2003).

Usage

```
npudens(bws, ...)
```

```
## S3 method for class 'formula'
npudens(bws, data = NULL, newdata = NULL, ...)
```

```
## S3 method for class 'bandwidth'
npudens(bws,
        tdat = stop("invoked without training data 'tdat'"),
        edat,
        ...)
```

```
## S3 method for class 'call'
npudens(bws, ...)
```

```
## Default S3 method:
npudens(bws, tdat, ...)
```

Arguments

bws	a bandwidth specification. This can be set as a bandwidth object returned from an invocation of npudensbw , or as a p -vector of bandwidths, with an element for each variable in the training data. If specified as a vector, then additional arguments will need to be supplied as necessary to change them from the defaults to specify the bandwidth type, kernel types, training data, and so on.
...	additional arguments supplied to specify, the training data, the bandwidth type, kernel types, and so on. This is necessary if you specify bws as a p -vector and not a bandwidth object, and you do not desire the default behaviours. To do this, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> , as described in npudensbw .
tdat	a p -variate data frame of sample realizations (training data) used to estimate the density. Defaults to the training data used to compute the bandwidth object.
edat	a p -variate data frame of density evaluation points. By default, evaluation takes place on the data provided by tdat.

data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(bws)</code> , typically the environment from which <code>npudensbw</code> was called.
newdata	An optional data frame in which to look for evaluation data. If omitted, the training data are used.

Details

Typical usages are (see below for a complete list of options and also the examples at the end of this help file)

Usage 1: first compute the bandwidth object via `npudensbw` and then compute the density:

```
bw <- npudensbw(~y)
fhat <- npudens(bw)
```

Usage 2: alternatively, compute the bandwidth object indirectly:

```
fhat <- npudens(~y)
```

Usage 3: modify the default kernel and order:

```
fhat <- npudens(~y, ckertype="epanechnikov", ckerorder=4)
```

Usage 4: use the data frame interface rather than the formula interface:

```
fhat <- npudens(tdat = y, ckertype="epanechnikov", ckerorder=4)
```

`npudens` implements a variety of methods for estimating multivariate density functions (p -variate) defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

Data contained in the data frame `tdat` (and also `edat`) may be a mix of continuous (default), unordered discrete (to be specified in the data frame `tdat` using the `factor` command), and ordered discrete (to be specified in the data frame `tdat` using the `ordered` command). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see [np](#) for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the

uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken's (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

npudens returns a npdensity object. The generic accessor functions `fitted`, and `se`, extract estimated values and asymptotic standard errors on estimates, respectively, from the returned object. Furthermore, the functions `predict`, `summary` and `plot` support objects of both classes. The returned objects have the following components:

<code>eval</code>	the evaluation points.
<code>dens</code>	estimation of the density at the evaluation points
<code>derr</code>	standard errors of the density estimates
<code>log_likelihood</code>	log likelihood of the density estimates

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by <code>as.data.frame</code>) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
dat	a p -variate data frame on which bandwidth selection will be performed. The data types may be continuous, discrete (unordered and ordered factors), or some combination thereof.
bws	a bandwidth specification. This can be set as a bandwidth object returned from a previous invocation, or as a vector of bandwidths, with each element i cor-

	responding to the bandwidth for column i in <code>dat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
<code>...</code>	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.
<code>bwmethod</code>	a character string specifying the bandwidth selection method. <code>cv.ml</code> specifies likelihood cross-validation, <code>cv.ls</code> specifies least-squares cross-validation, and <code>normal-reference</code> just computes the ‘rule-of-thumb’ bandwidth h_j using the standard formula $h_j = 1.06\sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation, mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. Note that when there exist factors and the normal-reference rule is used, there is zero smoothing of the factors. Defaults to <code>cv.ml</code> .
<code>bwscaling</code>	a logical value that when set to <code>TRUE</code> the supplied bandwidths are interpreted as ‘scale factors’ (c_j), otherwise when the value is <code>FALSE</code> they are interpreted as ‘raw bandwidths’ (h_j for continuous data types, λ_j for discrete data types). For continuous data types, c_j and h_j are related by the formula $h_j = c_j \sigma_j n^{-1/(2P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation, mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(2P+l)}$, where here j denotes discrete variable j . Defaults to <code>FALSE</code> .
<code>bwtype</code>	character string used for the continuous variable bandwidth type, specifying the type of bandwidth to compute and return in the bandwidth object. Defaults to <code>fixed</code> . Option summary: <code>fixed</code> : compute fixed bandwidths <code>generalized_nn</code> : compute generalized nearest neighbors <code>adaptive_nn</code> : compute adaptive nearest neighbors
<code>bandwidth.compute</code>	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to <code>FALSE</code> , a bandwidth object will be returned with bandwidths set to those specified in <code>bws</code> . Defaults to <code>TRUE</code> .
<code>ckertype</code>	character string used to specify the continuous kernel type. Can be set as <code>gaussian</code> , <code>epanechnikov</code> , or <code>uniform</code> . Defaults to <code>gaussian</code> .
<code>ckerorder</code>	numeric value specifying kernel order (one of (2, 4, 6, 8)). Kernel order specified along with a <code>uniform</code> continuous kernel type will be ignored. Defaults to 2.
<code>ukertype</code>	character string used to specify the unordered categorical kernel type. Can be set as <code>aitchisonaitken</code> or <code>liracine</code> .
<code>okertype</code>	character string used to specify the ordered categorical kernel type. Can be set as <code>wangvanryzin</code> or <code>liracine</code> .

<code>nmulti</code>	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points.
<code>remin</code>	a logical value which when set as TRUE the search routine restarts from located minima for a minor gain in accuracy. Defaults to TRUE.
<code>itmax</code>	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
<code>ftol</code>	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01*\sqrt{.Machine\$double.eps}$).
<code>tol</code>	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine's floating point precision). Defaults to $1.490116e-04$ ($1.0e+04*\sqrt{.Machine\$double.eps}$).
<code>small</code>	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\sqrt{\text{epsilon}}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision)). Defaults to <code>small = 1.490116e-05</code> ($1.0e+03*\sqrt{.Machine\$double.eps}$).
<code>lbc.dir, dfc.dir, cfac.dir, initc.dir</code>	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
<code>lbd.dir, hbd.dir, dfac.dir, initd.dir</code>	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details
<code>lbc.init, hbc.init, cfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for numeric variables for Powell's algorithm. See Details
<code>lbd.init, hbd.init, dfac.init</code>	lower bound, upper bound, and non-random initial values for scale factors for categorical variables for Powell's algorithm. See Details
<code>scale.init.categorical.sample</code>	a logical value that when set to TRUE scales <code>lbd.dir</code> , <code>hbd.dir</code> , <code>dfac.dir</code> , and <code>initd.dir</code> by $n^{-2/(2P+l)}$, n the number of observations, P the order of the kernel, and l the number of numeric variables. See Details

Details

Typical usages are (see below for a complete list of options and also the examples at the end of this help file)

Usage 1: compute a bandwidth object using the formula interface:

```
bw <- npudensbw(~y)
```

Usage 2: compute a bandwidth object using the data frame interface and change the default kernel and order:

```
fhat <- npudensbw(tdat = y, ckertype="epanechnikov", ckerorder=4)
```

npudensbw implements a variety of methods for choosing bandwidths for multivariate (p -variate) distributions defined over a set of possibly continuous and/or discrete (unordered, ordered) data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

The cross-validation methods employ multivariate numerical search algorithms (direction set (Powell’s) methods in multidimensions).

Bandwidths can (and will) differ for each variable which is, of course, desirable.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the density at the point x . Generalized nearest-neighbor bandwidths change with the point at which the density is estimated, x . Fixed bandwidths are constant over the support of x .

npudensbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the `dat` parameter. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `dat` may be a mix of continuous (default), unordered discrete (to be specified in the data frame `dat` using `factor`), and ordered discrete (to be specified in the data frame `dat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form `~ data`, where `data` is a series of variables specified by name, separated by the separation character `+`. For example, `~ x + y` specifies that the bandwidths for the joint distribution of variables `x` and `y` are to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth order Gaussian and Epanechnikov kernels, and the uniform kernel. Unordered discrete data types use a variation on Aitchison and Aitken’s (1976) kernel, while ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The optimizer invoked for search is Powell’s conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and, when restarting, random values for successive invocations. Bandwidths for `numeric` variables are scaled by robust measures of spread, the sample size, and the number of `numeric` variables where appropriate. Two sets of parameters for bandwidths for `numeric` can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell’s algorithm does not involve explicit computation of the function’s gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable ‘tuning’ for various methods rather than for the user themselves.

Value

npudensbw returns a bandwidth object, with the following components:

bw	bandwidth(s), scale factor(s) or nearest neighbours for the data, dat
fval	objective function value at minimum

if bwtype is set to fixed, an object containing bandwidths, of class bandwidth (or scale factors if bwscaling = TRUE) is returned. If it is set to generalized_nn or adaptive_nn, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables. Bandwidths are stored under the component name bw, with each element i corresponding to column i of input data dat.

The functions `predict`, `summary` and `plot` support objects of type bandwidth.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(dat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

 npudist

Kernel Distribution Estimation with Mixed Data Types

Description

npudist computes kernel unconditional cumulative distribution estimates on evaluation data, given a set of training data and a bandwidth specification (a dbandwidth object or a bandwidth vector, bandwidth type, and kernel type) using the method of Li and Racine (2013).

Usage

```

npudist(bws, ...)

## S3 method for class 'formula'
npudist(bws, data = NULL, newdata = NULL, ...)

## S3 method for class 'dbandwidth'
npudist(bws,
        tdat = stop("invoked without training data 'tdat'"),
        edat,
        ...)

## S3 method for class 'call'
npudist(bws, ...)

## Default S3 method:
npudist(bws, tdat, ...)

```

Arguments

bws a dbandwidth specification. This can be set as a dbandwidth object returned from an invocation of `npudistbw`, or as a p -vector of bandwidths, with an element for each variable in the training data. If specified as a vector, then additional arguments will need to be supplied as necessary to change them from the defaults to specify the bandwidth type, kernel types, training data, and so on.

...	additional arguments supplied to specify the training data, the bandwidth type, kernel types, and so on. This is necessary if you specify <i>bws</i> as a p -vector and not a <i>dbandwidth</i> object, and you do not desire the default behaviours. To do this, you may specify any of <i>bwscaling</i> , <i>bwtype</i> , <i>ckertype</i> , <i>ckerorder</i> , <i>okertype</i> , as described in npudistbw .
<i>tdat</i>	a p -variate data frame of sample realizations (training data) used to estimate the cumulative distribution. Defaults to the training data used to compute the bandwidth object.
<i>edat</i>	a p -variate data frame of cumulative distribution evaluation points. By default, evaluation takes place on the data provided by <i>tdat</i> .
<i>data</i>	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in <i>data</i> , the variables are taken from <code>environment(bws)</code> , typically the environment from which npudistbw was called.
<i>newdata</i>	An optional data frame in which to look for evaluation data. If omitted, the training data are used.

Details

Typical usages are (see below for a complete list of options and also the examples at the end of this help file)

Usage 1: first compute the bandwidth object via `npudistbw` and then compute the cumulative distribution:

```
bw <- npudistbw(~y)
Fhat <- npudist(bw)
```

Usage 2: alternatively, compute the bandwidth object indirectly:

```
Fhat <- npudist(~y)
```

Usage 3: modify the default kernel and order:

```
Fhat <- npudist(~y, ckertype="epanechnikov", ckerorder=4)
```

Usage 4: use the data frame interface rather than the formula interface:

```
Fhat <- npudist(tdat = y, ckertype="epanechnikov", ckerorder=4)
```

`npudist` implements a variety of methods for estimating multivariate cumulative distributions (p -variate) defined over a set of possibly continuous and/or discrete (ordered) data. The approach is based on Li and Racine (2003) who employ ‘generalized product kernels’ that admit a mix of continuous and discrete data types.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change

with each sample realization in the set, x_i , when estimating the cumulative distribution at the point x . Generalized nearest-neighbor bandwidths change with the point at which the cumulative distribution is estimated, x . Fixed bandwidths are constant over the support of x .

Data contained in the data frame `tdata` (and also `edata`) may be a mix of continuous (default) and ordered discrete (to be specified in the data frame `tdata` using the `ordered` command). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth-order Gaussian and Epanechnikov kernels, and the uniform kernel. Ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

Value

`npudist` returns a `npdistribution` object. The generic accessor functions `fitted` and `se` extract estimated values and asymptotic standard errors on estimates, respectively, from the returned object. Furthermore, the functions `predict`, `summary` and `plot` support objects of both classes. The returned objects have the following components:

<code>eval</code>	the evaluation points.
<code>dist</code>	estimate of the cumulative distribution at the evaluation points
<code>derr</code>	standard errors of the cumulative distribution estimates

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

```

Arguments

formula	a symbolic description of variables on which bandwidth selection is to be performed. The details of constructing a formula are described below.
data	an optional data frame, list or environment (or object coercible to a data frame by as.data.frame) containing the variables in the model. If not found in data, the variables are taken from <code>environment(formula)</code> , typically the environment from which the function is called.
subset	an optional vector specifying a subset of observations to be used in the fitting

	process.
na.action	a function which indicates what should happen when the data contain NAs. The default is set by the <code>na.action</code> setting of options, and is <code>na.fail</code> if that is unset. The (recommended) default is <code>na.omit</code> .
call	the original function call. This is passed internally by <code>np</code> when a bandwidth search has been implied by a call to another function. It is not recommended that the user set this.
gdata	a grid of data on which the indicator function for least-squares cross-validation is to be computed (can be the sample or a grid of quantiles).
dat	a p -variate data frame on which bandwidth selection will be performed. The data types may be continuous, discrete (ordered factors), or some combination thereof.
bws	a bandwidth specification. This can be set as a bandwidth object returned from a previous invocation, or as a vector of bandwidths, with each element i corresponding to the bandwidth for column i in <code>dat</code> . In either case, the bandwidth supplied will serve as a starting point in the numerical search for optimal bandwidths. If specified as a vector, then additional arguments will need to be supplied as necessary to specify the bandwidth type, kernel types, selection methods, and so on. This can be left unset.
gdat	a grid of data on which the indicator function for least-squares cross-validation is to be computed (can be the sample or a grid of quantiles).
...	additional arguments supplied to specify the bandwidth type, kernel types, selection methods, and so on, detailed below.
bwmethod	a character string specifying the bandwidth selection method. <code>cv.cdf</code> specifies least-squares cross-validation for cumulative distribution functions (Li and Racine (2013)), and <code>normal-reference</code> just computes the ‘rule-of-thumb’ bandwidth h_j using the standard formula $h_j = 1.587\sigma_j n^{-1/(P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation, mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. Note that when there exist factors and the normal-reference rule is used, there is zero smoothing of the factors. Defaults to <code>cv.cdf</code> .
bwscaling	a logical value that when set to <code>TRUE</code> the supplied bandwidths are interpreted as ‘scale factors’ (c_j), otherwise when the value is <code>FALSE</code> they are interpreted as ‘raw bandwidths’ (h_j for continuous data types, λ_j for discrete data types). For continuous data types, c_j and h_j are related by the formula $h_j = c_j \sigma_j n^{-1/(P+l)}$, where σ_j is an adaptive measure of spread of the j th continuous variable defined as $\min(\text{standard deviation, mean absolute deviation}/1.4826, \text{interquartile range}/1.349)$, n the number of observations, P the order of the kernel, and l the number of continuous variables. For discrete data types, c_j and h_j are related by the formula $h_j = c_j n^{-2/(P+l)}$, where here j denotes discrete variable j . Defaults to <code>FALSE</code> .
bwtype	character string used for the continuous variable bandwidth type, specifying the type of bandwidth to compute and return in the bandwidth object. Defaults to <code>fixed</code> . Option summary: fixed: compute fixed bandwidths

	generalized_nn: compute generalized nearest neighbors
	adaptive_nn: compute adaptive nearest neighbors
bandwidth.compute	a logical value which specifies whether to do a numerical search for bandwidths or not. If set to FALSE, a bandwidth object will be returned with bandwidths set to those specified in bws. Defaults to TRUE.
ckertype	character string used to specify the continuous kernel type. Can be set as gaussian, epanechnikov, or uniform. Defaults to gaussian.
ckerorder	numeric value specifying kernel order (one of (2, 4, 6, 8)). Kernel order specified along with a uniform continuous kernel type will be ignored. Defaults to 2.
okertype	character string used to specify the ordered categorical kernel type. Can be set as wangvanryzin.
nmulti	integer number of times to restart the process of finding extrema of the cross-validation function from different (random) initial points.
remin	a logical value which when set as TRUE the search routine restarts from located minima for a minor gain in accuracy. Defaults to TRUE.
itmax	integer number of iterations before failure in the numerical optimization routine. Defaults to 10000.
do.full.integral	a logical value which when set as TRUE evaluates the moment-based integral on the entire sample. Defaults to FALSE.
ngrid	integer number of grid points to use when computing the moment-based integral. Defaults to 100.
ftol	fractional tolerance on the value of the cross-validation function evaluated at located minima (of order the machine precision or perhaps slightly larger so as not to be diddled by roundoff). Defaults to $1.490116e-07$ ($1.0e+01*\sqrt{.Machine\$double.eps}$).
tol	tolerance on the position of located minima of the cross-validation function (tol should generally be no smaller than the square root of your machine's floating point precision). Defaults to $1.490116e-04$ ($1.0e+04*\sqrt{.Machine\$double.eps}$).
small	a small number used to bracket a minimum (it is hopeless to ask for a bracketing interval of width less than $\sqrt{\epsilon}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision)). Defaults to $small = 1.490116e-05$ ($1.0e+03*\sqrt{.Machine\$double.eps}$).
lbc.dir, dfc.dir, cfac.dir, initc.dir	lower bound, chi-square degrees of freedom, stretch factor, and initial non-random values for direction set search for Powell's algorithm for numeric variables. See Details
lbd.dir, hbd.dir, dfac.dir, initd.dir	lower bound, upper bound, stretch factor, and initial non-random values for direction set search for Powell's algorithm for categorical variables. See Details
lbc.init, hbc.init, cfac.init	lower bound, upper bound, and non-random initial values for scale factors for numeric variables for Powell's algorithm. See Details

lbd.init, hbd.init, dfac.init	lower bound, upper bound, and non-random initial values for scale factors for categorical variables for Powell's algorithm. See Details
scale.init.categorical.sample	a logical value that when set to TRUE scales lbd.dir, hbd.dir, dfac.dir, and initd.dir by $n^{-2/(2P+l)}$, n the number of observations, P the order of the kernel, and l the number of numeric variables. See Details
memfac	The algorithm to compute the least-squares objective function uses a block-based algorithm to eliminate or minimize redundant kernel evaluations. Due to memory, hardware and software constraints, a maximum block size must be imposed by the algorithm. This block size is roughly equal to memfac*10 ⁵ elements. Empirical tests on modern hardware find that a memfac of 500 performs well. If you experience out of memory errors, or strange behaviour for large data sets (>100k elements) setting memfac to a lower value may fix the problem.

Details

Typical usages are (see below for a complete list of options and also the examples at the end of this help file)

Usage 1: compute a bandwidth object using the formula interface:

```
bw <- npudistbw(~y)
```

Usage 2: compute a bandwidth object using the data frame interface and change the default kernel and order:

```
Fhat <- npudistbw(tdat = y, ckertype="epanechnikov", ckerorder=4)
```

npudistbw implements a variety of methods for choosing bandwidths for multivariate (p -variate) distributions defined over a set of possibly continuous and/or discrete (ordered) data. The approach is based on Li and Racine (2003) who employ 'generalized product kernels' that admit a mix of continuous and discrete data types.

The cross-validation methods employ multivariate numerical search algorithms (direction set (Powell's) methods in multidimensions).

Bandwidths can (and will) differ for each variable which is, of course, desirable.

Three classes of kernel estimators for the continuous data types are available: fixed, adaptive nearest-neighbor, and generalized nearest-neighbor. Adaptive nearest-neighbor bandwidths change with each sample realization in the set, x_i , when estimating the cumulative distribution at the point x . Generalized nearest-neighbor bandwidths change with the point at which the cumulative distribution is estimated, x . Fixed bandwidths are constant over the support of x .

npudistbw may be invoked *either* with a formula-like symbolic description of variables on which bandwidth selection is to be performed *or* through a simpler interface whereby data is passed directly to the function via the dat parameter. Use of these two interfaces is **mutually exclusive**.

Data contained in the data frame `dat` may be a mix of continuous (default) and ordered discrete (to be specified in the data frame `dat` using `ordered`). Data can be entered in an arbitrary order and data types will be detected automatically by the routine (see `np` for details).

Data for which bandwidths are to be estimated may be specified symbolically. A typical description has the form `~ data`, where `data` is a series of variables specified by name, separated by the separation character `'+'`. For example, `~ x + y` specifies that the bandwidths for the joint distribution of variables `x` and `y` are to be estimated. See below for further examples.

A variety of kernels may be specified by the user. Kernels implemented for continuous data types include the second, fourth, sixth, and eighth-order Gaussian and Epanechnikov kernels, and the uniform kernel. Ordered data types use a variation of the Wang and van Ryzin (1981) kernel.

The optimizer invoked for search is Powell's conjugate direction method which requires the setting of (non-random) initial values and search directions for bandwidths, and when restarting, random values for successive invocations. Bandwidths for numeric variables are scaled by robust measures of spread, the sample size, and the number of numeric variables where appropriate. Two sets of parameters for bandwidths for numeric can be modified, those for initial values for the parameters themselves, and those for the directions taken (Powell's algorithm does not involve explicit computation of the function's gradient). The default values are set by considering search performance for a variety of difficult test cases and simulated cases. We highly recommend restarting search a large number of times to avoid the presence of local minima (achieved by modifying `nmulti`). Further refinement for difficult cases can be achieved by modifying these sets of parameters. However, these parameters are intended more for the authors of the package to enable 'tuning' for various methods rather than for the user them self.

Value

`npudistbw` returns a bandwidth object with the following components:

<code>bw</code>	bandwidth(s), scale factor(s) or nearest neighbours for the data, <code>dat</code>
<code>fval</code>	objective function value at minimum

if `bwtype` is set to `fixed`, an object containing bandwidths, of class `bandwidth` (or scale factors if `bwscaling = TRUE`) is returned. If it is set to `generalized_nn` or `adaptive_nn`, then instead the k th nearest neighbors are returned for the continuous variables while the discrete kernel bandwidths are returned for the discrete variables. Bandwidths are stored under the component name `bw`, with each element i corresponding to column i of input data `dat`.

The functions `predict`, `summary` and `plot` support objects of type `bandwidth`.

Usage Issues

If you are using data of mixed types, then it is advisable to use the `data.frame` function to construct your input data and not `cbind`, since `cbind` will typically not work as intended on mixed data types and will coerce the data to the same type.

Caution: multivariate data-driven bandwidth selection methods are, by their nature, *computationally intensive*. Virtually all methods require dropping the i th observation from the data set, computing an object, repeating this for all observations in the sample, then averaging each of these leave-one-out estimates for a *given* value of the bandwidth vector, and only then repeating this a large number of times in order to conduct multivariate numerical minimization/maximization. Furthermore, due

to the potential for local minima/maxima, *restarting this procedure a large number of times may often be necessary*. This can be frustrating for users possessing large datasets. For exploratory purposes, you may wish to override the default search tolerances, say, setting `ftol=.01` and `tol=.01` and conduct multistarting (the default is to restart `min(5, ncol(dat))` times) as is done for a number of examples. Once the procedure terminates, you can restart search with default tolerances using those bandwidths obtained from the less rigorous search (i.e., set `bws=bw` on subsequent calls to this routine where `bw` is the initial bandwidth object). A version of this package using the `Rmpi` wrapper is under development that allows one to deploy this software in a clustered computing environment to facilitate computation involving large datasets.

detach(Italy)

## End(Not run)
```

Description

npunitest implements the consistent metric entropy test of Maasoumi and Racine (2002) for two arbitrary, stationary univariate nonparametric densities on common support.

Usage

```
npunitest(data.x = NULL,
          data.y = NULL,
          method = c("integration", "summation"),
          bootstrap = TRUE,
          boot.num = 399,
          bw.x = NULL,
          bw.y = NULL,
          random.seed = 42,
          ...)
```

Arguments

data.x, data.y	common support univariate vectors containing the variables.
method	a character string used to specify whether to compute the integral version or the summation version of the statistic. Can be set as <code>integration</code> or <code>summation</code> . Defaults to <code>integration</code> . See ‘Details’ below for important information regarding the use of summation when <code>data.x</code> and <code>data.y</code> lack common support and/or are sparse.
bootstrap	a logical value which specifies whether to conduct the bootstrap test or not. If set to <code>FALSE</code> , only the statistic will be computed. Defaults to <code>TRUE</code> .
boot.num	an integer value specifying the number of bootstrap replications to use. Defaults to 399.
bw.x, bw.y	numeric (scalar) bandwidths. Defaults to plug-in (see details below).
random.seed	an integer used to seed R’s random number generator. This is to ensure replicability. Defaults to 42.
...	additional arguments supplied to specify the bandwidth type, kernel types, and so on. This is used since we specify <code>bw</code> as a numeric scalar and not a bandwidth object, and is of interest if you do not desire the default behaviours. To change the defaults, you may specify any of <code>bwscaling</code> , <code>bwtype</code> , <code>ckertype</code> , <code>ckerorder</code> , <code>ukertype</code> , <code>okertype</code> .

Details

npunitest computes the nonparametric metric entropy (normalized Hellinger of Granger, Maasoumi and Racine (2004)) for testing equality of two univariate density/probability functions, $D[f(x), f(y)]$. See Maasoumi and Racine (2002) for details. Default bandwidths are of the plug-in variety ([bw.SJ](#) for continuous variables and direct plug-in for discrete variables). The bootstrap is conducted via simple resampling with replacement from the pooled `data.x` and `data.y` (`data.x` only for summation).

The summation version of this statistic can be numerically unstable when `data.x` and `data.y` lack common support or when the overlap is sparse (the summation version involves division of densities

while the integration version involves differences, and the statistic in such cases can be reported as exactly 0.5 or 0). Warning messages are produced when this occurs ('integration recommended') and should be heeded.

Numerical integration can occasionally fail when the `data.x` and `data.y` distributions lack common support and/or lie an extremely large distance from one another (the statistic in such cases will be reported as exactly 0.5 or 0). However, in these extreme cases, simple tests will reveal the obvious differences in the distributions and entropy-based tests for equality will be clearly unnecessary.

Value

`npunitest` returns an object of type `unitest` with the following components

<code>Srho</code>	the statistic <code>Srho</code>
<code>Srho.bootstrap</code>	contains the bootstrap replications of <code>Srho</code>
<code>P</code>	the P-value of the statistic
<code>boot.num</code>	number of bootstrap replications
<code>bw.x</code> , <code>bw.y</code>	scalar bandwidths for <code>data.x</code> , <code>data.y</code>

[summary](#) supports object of type `unitest`.

Usage Issues

See the example below for proper usage.

oecdpanel

Cross Country Growth Panel

Description

Cross country GDP growth panel covering the period 1960-1995 used by Liu and Stengos (2000) and Maasoumi, Racine, and Stengos (2007). There are 616 observations in total. `data("oecdpanel")` makes available the dataset "oecdpanel" plus an additional object "bw".

Usage

```
data("oecdpanel")
```

Format

A data frame with 7 columns, and 616 rows. This panel covers 7 5-year periods: 1960-1964, 1965-1969, 1970-1974, 1975-1979, 1980-1984, 1985-1989 and 1990-1994.

A separate local-linear rbandwidth object ('bw') has been computed for the user's convenience which can be used to visualize this dataset using `plot(bw)`.

growth the first column, of type numeric: growth rate of real GDP per capita for each 5-year period

- oecd** the second column, of type factor: equal to 1 for OECD members, 0 otherwise
- year** the third column, of type integer
- initgdp** the fourth column, of type numeric: per capita real GDP at the beginning of each 5-year period
- popgro** the fifth column, of type numeric: average annual population growth rate for each 5-year period
- inv** the sixth column, of type numeric: average investment/GDP ratio for each 5-year period
- humancap** the seventh column, of type numeric: average secondary school enrolment rate for each 5-year period

se	<i>Extract Standard Errors</i>
----	--------------------------------

Description

se is a generic function which extracts standard errors from objects.

Usage

```
se(x)
```

Arguments

- x an object for which the extraction of standard errors is meaningful.
- ... other arguments.

Details

This function provides a generic interface for extraction of standard errors from objects.

Value

Standard errors extracted from the model object `x`.

Note

This method currently only supports objects from the `np` library.

Author(s)

Tristen Hayfield <tristen.hayfield@gmail.com>, Jeffrey S. Racine <racinej@mcmaster.ca>

See Also

`fitted`, `residuals`, `coef`, and `gradients`, for related methods; `np` for supported objects.

Examples

```
x <- rnorm(10)
se(npudens(npudensbw(~x)))
```

`uocquantile`*Compute Quantiles*

Description

`uocquantile` is a function which computes quantiles of an unordered, ordered or continuous variable `x`.

Usage

```
uocquantile(x, prob)
```

Arguments

<code>x</code>	an ordered, unordered or continuous variable.
<code>prob</code>	quantile to compute.

Details

`uocquantile` is a function which computes quantiles of an unordered, ordered or continuous variable `x`. If `x` is unordered, the mode is returned. If `x` is ordered, the level for which the cumulative distribution is \geq `prob` is returned. If `x` is continuous, `quantile` is invoked and the result returned.

Value

A quantile computed from `x`.

Author(s)

Tristen Hayfield <tristen.hayfield@gmail.com>, Jeffrey S. Racine <racinej@mcmaster.ca>

See Also

[quantile](#)

Examples

```
x <- rbinom(n = 100, size = 10, prob = 0.5)
uocquantile(x, 0.5)
```

wage1

Cross-Sectional Data on Wages

Description

Cross-section wage data consisting of a random sample taken from the U.S. Current Population Survey for the year 1976. There are 526 observations in total. `data("wage1")` makes available the dataset "wage" plus additional objects "bw.all" and "bw.subset".

Usage

```
data("wage1")
```

Format

A data frame with 24 columns, and 526 rows.

Two local-linear rbandwidth objects ('bw.all' and 'bw.subset') have been computed for the user's convenience which can be used to visualize this dataset using `plot(bw.all)`

wage column 1, of type numeric, average hourly earnings

educ column 2, of type numeric, years of education

exper column 3, of type numeric, years potential experience

tenure column 4, of type numeric, years with current employer

nonwhite column 5, of type factor, ="Nonwhite" if nonwhite, "White" otherwise

female column 6, of type factor, ="Female" if female, "Male" otherwise

married column 7, of type factor, ="Married" if Married, "Nonmarried" otherwise

numdep column 8, of type numeric, number of dependants

smsa column 9, of type numeric, =1 if live in SMSA

northcen column 10, of type numeric, =1 if live in north central U.S

south column 11, of type numeric, =1 if live in southern region

west column 12, of type numeric, =1 if live in western region

construc column 13, of type `numeric`, =1 if work in construction industry
ndurman column 14, of type `numeric`, =1 if in non-durable manufacturing industry
trcommpu column 15, of type `numeric`, =1 if in transportation, communications, public utility
trade column 16, of type `numeric`, =1 if in wholesale or retail
services column 17, of type `numeric`, =1 if in services industry
profserv column 18, of type `numeric`, =1 if in professional services industry
profocc column 19, of type `numeric`, =1 if in professional occupation
clerocc column 20, of type `numeric`, =1 if in clerical occupation
servocc column 21, of type `numeric`, =1 if in service occupation
lwage column 22, of type `numeric`, $\log(\text{wage})$
expersq column 23, of type `numeric`, exper^2
tenursq column 24, of type `numeric`, tenure^2
