Type Package

Title Time-Dependent ROC Curve Estimators and Expected Utility Functions

Version 0.9.4

Date 2016-03-09

Author Y. Foucher, E. Dantan, P. Tessier, F. Le Borgne, and M. Lorent

Maintainer Y. Foucher <yohann.foucher@univ-nantes.fr>

Description Contains functions in order to estimate diagnostic and prognostic capacities of continuous markers. More precisely, one function concerns the estimation of time-dependent ROC (RO Ct) curve, as proposed by Heagerty et al. (2000) <DOI: 10.1111/j.0006-341X.2000.00337.x>. One function concerns the adaptation of the RO Ct theory for studying the capacity of a marker to predict the excess of mortality of a specific population compared to the general population. This last part is based on additive relative survival models and the work of Pohar-Perme et al. (2012) <DOI: 10.1111/j.1541-0420.2011.01640.x>. We also propose two functions for cut-off estimation in medical decision making by maximizing time-dependent expected utility function. Finally, we propose confounder-adjusted estimators of ROC and RO Ct curves by using the Inverse Probability Weighting (IPW) approach. For the confounder-adjusted ROC curve (without censoring), we also proposed the implementation of the estimator based on placement values proposed by Pepe and Cai (2004) <DOI: 10.1111/j.0006-341X.2004.00200.x>.

  ROCt-package

   2
Time-Dependent ROC Curve Estimators and Expected Utility Functions.

Description

Compute ROC curve and expected utility for medical decision making, with and without censoring.

Details

Package: ROCt
Type: Package
Version: 0.9.4
Date: 2016-03-09
License: GPL (>=2)
LazyLoad: yes

Several functions are available:

- **crude.ROCt**: This function allows the estimation of a crude time-dependent ROC curve, respecting the definition proposed by Heagerty et al. (2000).
- **net.ROCt**: This function allows the estimation of net time-dependent ROC curve, i.e. when the only cause of death is due to the disease.
- **EUt**: The expected utility theory allows the estimation of optimal cut-off for medical decision making.
- **AUC**: This function computes the area under ROC curve using the trapezoidal rule based on two vectors of sensitivities and specificities.
- **adjusted.ROC**: This function allows for the estimation of ROC curve by taking into account possible confounding factors (IPW or placement values estimators).
- **adjusted.ROCt**: This function allows for the estimation of time-dependent ROC curve by taking into account possible confounding factors (IPW estimator).

adjusted.ROC function

Confounders-Adjusted ROC Curves Without Right Censored Data.

Description

This function allows for the estimation of ROC curve by taking into account possible confounding factors (IPW or placement values estimators).

Usage

adjusted.ROC(status, variable, confounders, database, precision, estimator)

Arguments

status A character string with the name of the variable in database which represents the disease status indicator (for instance: 0=healthy, 1=diseased).

variable A character string with the name of the variable in database which represents the diagnostic/prognostic variable under interest.

confounders An object of class "formula". More precisely only the right part with an expression of the form ~ model, where model is the linear predictor of the logistic regressions performed for each cut-off value. The user can use ~1 to obtain the crude estimation.

database An object of the class data.frame containing the variables previously detailed.

precision A numeric vector with values between 0 and 1. The values represent the x-axis (1-specificity) of the ROC graph for which the user want to obtain the corresponding sensitivities. 0 and 1 are not allowed.

estimator Two possible estimators can be used: "ipw" and "pv". IPW is based on the Inverse Probability Weighting theory as proposed by Le Borgne et al. (2015). The IPW estimator is selected by default. The user can also use the placement values estimator as proposed by Pepe and Cai (Biometrics, 2004).
Details

This function computes confounder-adjusted ROC curve for uncensored data. We adapted the usual estimator by considering the probability for a patient to have a prognostic variable higher than a given cut-off value, given the possible confounding factors. This estimator is obtained by using "ipw" in the option estimator. The user can also use the estimator first proposed by Pepe and Cai (2004) which is based on placement values.

Value

- **table**: This data frame presents the sensitivities and specificities.
- **auc**: The area under the ROC curve.

```

---

### adjusted.ROCT

**Confounders-Adjusted Time-Dependent ROC Curves With Right Censored Data.**

### Description

This function allows for the estimation of time-dependent ROC curve by taking into account possible confounding factors (IPW estimator).

### Usage

```r
adjusted.ROCT(times, failures, variable, confounders, database, pro.time, precision)
```

### Arguments

- **times**: A character string with the name of the variable in database which represents the follow up times.
- **failures**: A character string with the name of the variable in database which represents the event indicator (0=right censored, 1=event).
- **variable**: A character string with the name of the variable in database which represents the prognostic variable under interest. This variable is collected at the baseline.
- **confounders**: An object of class "formula". More precisely only the right part with an expression of the form ~ model, where model is the linear predictor of the logistic regressions performed for each cut-off value. The user can use ~1 to obtain the crude estimation.
- **database**: An object of the class data.frame containing the variables previously detailed.
- **pro.time**: The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument times.
- **precision**: The quintiles (between 0 and 1) of the prognostic variable used for computing each point of the time dependent ROC curve. 0 (min) and 1 (max) are not allowed.
Details

This function computes confounder-adjusted time-dependent ROC curve with right-censored data. We adapted the naive IPCW estimator as explained by Blanche, Dartigues and Jacqmin-Gadda (2013) by considering the probability for a patient to have a prognostic variable higher than a given cut-off value, given the possible confounding factors.

Value

table This data frame presents the sensitivities and specificities associated with the cut-off values.

auc The area under the time-dependent ROC curve for a prognostic up to pro.time.

Examples

# import and attach the data example
data(dataDIVAT)

# The confounder-adjusted time-dependent ROC curve to evaluate the capacities of the recipient age for the prognosis of post kidney transplant mortality up to 2500 days by taking into account the donor age and the recipient gender.
roc2 <- adjusted.ROCe(times="death.time", failures="death", variable="ageR", confounders=~bs(ageD, df=3) + sexeR, database=dataDIVAT, pro.time=2500, precision=seq(0.1, 0.9, by=0.2))

# The corresponding ROC graph
plot(1-roc2$table$sp, roc2$table$se, ylim=c(0,1), xlim=c(0,1), ylab="sensitivity", xlab="1-specificity", type="l", lty=1, col=1, lwd=2)
abline(c(0,0), c(1,1), lty=2)

# The corresponding AUC
roc2$auc
AUC

Area Under ROC Curve From Sensitivities And Specificities.

Description

This function computes the area under ROC curve by using the trapezoidal rule.

Usage

AUC(sens, spec)

Arguments

sens A numeric vector with the sensitivities
spec A numeric vector with the sensitivities

Details

This function computes the area under ROC curve using the trapezoidal rule. The value of the area is directly returned.

Author(s)

Y. Foucher <Yohann.Foucher@univ-nantes.fr>

Examples

se.temp <- c(0, 0.5, 0.5, 1)
sp.temp <- c(1, 0.5, 0.5, 0)
AUC(se.temp, sp.temp)

crude.ROCt

Time-Dependent ROC Curves With Right Censored Data.

Description

This function performs the characteristics of a time-dependent ROC curve based on k-nearest neighbor's (knn) estimator or only based on the Kaplan and Meier estimator.

Usage

crude.ROCt(times, failures, variable, pro.time, cut.off, estimator, prop)
Arguments

- **times**: A numeric vector with the follow up times.
- **failures**: A numeric vector with the event indicator (0=right censored, 1=event).
- **variable**: A numeric vector with the prognostic variable. This variable is collected at the baseline.
- **pro.time**: The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument time.
- **cut.off**: The cut-off values of the variable used to define the possible binary tests.
- **estimator**: Three possible estimators can be used: 'kaplan-meier', 'akritas' or 'naive'. The naive estimator is selected by default.
- **prop**: This is the unilateral proportion of the nearest neighbors. The estimation will be based on 2*prop (both right and left proportions) of the total sample size. This parameter will only be used if estimator='akritas'.

Details

This function computes time-dependent ROC curve with right-censored data. It can use Akritas approach (nearest neighbor’s estimation) for ensuring monotone increasing ROC curve, instead of the simple Kaplan-Meier estimator. This Akritas approach may be avoid if the sample size is large because of computing time. Both estimators were defined by Heagerty, Lumley and Pepe (2000). A third alternative is the use of the naive estimator as explained by Blanche, Dartigues and Jacqmin-Gadda (2013). This estimator is less time-consuming compared to the Akritas approach.

Value

- **table**: This data frame presents the sensitivities and specificities associated with the cut-off values. One can observe NA if the value cannot be computed.
- **auc**: The area under the time-dependent ROC curve for a prognostic up to prognostic time.
- **missing**: Number of deleted observations due to missing data.

dataDIVAT

A Sample Of The DIVAT Cohort (Mortality).

Description

A data frame with 4267 French kidney transplant recipients. The time-to-event is the time between the transplantation and the recipient death. This time can be right-censored. A vector of covariates
is also collected at the transplantation.

Usage

data(dataDIVAT)

Format

A data frame with 4267 observations (rows) with the 8 following variables (columns).

ageR  This numeric vector represents the age of the recipient (in years)
sexR  This numeric vector represents the gender of the recipient (1=men, 0=female)
year_nxtx This numeric vector represents the year of the transplantation
ante_diab This numeric vector represents the diabetes statute (1=yes, 0=no)
pra  This numeric vector represents the pre-graft immunization using the panel reactive antibody
     (1=detectable, 0=undetectable)
ageD  This numeric vector represents the age of the donor (in years)
death_time  This numeric vector represents the follow-up time in days (until death or censoring)
death  This numeric vector represents the death indicator at the follow-up end (1=death, 0=alive)

Details

The immunology and nephrology department of the Nantes University hospital constituted a data bank with the monitoring of medical records for kidney and/or pancreas transplant recipients. The associated software is called DIVAT. Here is a sample of 4267 patients. The time-to-event is the time between the transplantation and the death of the recipient. This time can be right-censored. A vector of covariates, all measured at the transplantation, is also collected for each patient.

Source

Examples

data(dataDIVAT)

### a short summary of the recipient age at the transplantation
summary(data$ageR)

### Kaplan and Meier estimation of the recipient survival
plot(survfit(Surv(death_time/365.25, death) ~ 1, data = dataDIVAT),
     xlab="Post transplantation time (in years)", ylab="Patient survival",
     mark.time=FALSE)
dataKTFS

Description

A data frame with 2169 French kidney transplant recipients. The time-to-event is the time between the transplantation and the return in dialysis. This time can be right-censored, especially at the time of the patient death with a functioning graft. The KTFS is a score proposed by Foucher et al. (2010) to stratify the recipients according to their risk of return in dialysis.

Usage

data(dataKTFS)

Format

A data frame with 2169 observations (raws) with the 3 following variables (columns).

- **time**: This numeric vector represents the follow up time in years (until return in dialysis or censoring)
- **failure**: This numeric vector represents the graft failure indicator at the follow-up end (1=return, 0=censoring)
- **score**: This numeric vector represents the KTFS values.

Details

The immunology and nephrology department of the Nantes University hospital constituted a data bank with the monitoring of medical records for kidney and/or pancreas transplant recipients. The associated software is called DIVAT. Here is the training sample of 2169 patients used for the construction of the KTFS, a scoring system proposed by Foucher et al. (2010) in order to stratify patients according to their risk of return in dialysis. The KTFS is based on 8 parameters collected during the first year post transplantation. Patients with a KTFS value higher than 4.17 were considered at high-risk.

```

---

**eut1**  
**Optimal Cut-Off Estimation Of A Prognostic Marker (Only One Group Is Observed).**

---

**Description**

This function allows the estimation of an optimal cut-off for medical decision making between two treatments A and B from a prognostic marker by maximizing the expected utility in a time-dependent context. Only the times-to-event of the group B are observed.

**Usage**

```r
eut1(times, failures, variable, pro.time, u.A0, u.A1, u.B0, u.B1, n.boot, rmst.change)
```

**Arguments**

- `times` A numeric vector with the follow up times for the patients receiving the treatment B.
- `failures` A numeric vector with the event indicator for the patients receiving the treatment B (0=right censoring, 1=event).
- `variable` A numeric vector with the observed values of the marker/variable under interest for the patients receiving the treatment B. This variable is collected at the baseline (times=0). By convention, we assume that patients with X>k will preferentially receive A, k being the optimal cut-off. In contrast, patients with X<k will receive preferentially B.
- `pro.time` The prognostic time for which the prognostic capacities of the marker and the patient outcomes are considered in the same unit than the one used in the argument `times`.
- `u.A0` A value of the utility of a patient receiving the treatment A before the event occurrence. This value should respect the 0-1 scale (from death to perfect health).
- `u.A1` A value of the utility of a patient receiving the treatment A after the event occurrence. This value should respect the 0-1 scale.
A value of the utility of a patient receiving the treatment B before the event occurrence. This value should respect the 0-1 scale.

A value of the utility of a patient receiving the treatment B after the event occurrence. This value should respect the 0-1 scale.

Number of bootstrap iterations to compute the 95% confidence interval of the optimal cut-off. The default value is NULL: no confidence interval is estimated.

A numeric vector with the expected relative change in the Restricted Mean Survival Time (RMST) by using the treatment A instead of the treatment B among patients with $x>k$.

This function computes the expected time-dependent utility. The data may be right-censored. The user has to define the utilities (qualities of life related to the possible health states). A positive test is defined by a marker value higher than the cut-off ($x>k$): by convention the patient will receive the treatment A. For example, the user has a cohort of patients receiving the treatment B. She(he) assumes that an alternative treatment A would be more convenient for patients with high-values of the marker X. She(he) aims to compute the optimal cut-off value for a future stratified medical decision rule: treatment A for patients with $x>k$ and treatment B for patients with $x<k$. The user has to enter the observed cohort of patients with the treatment B. Additional to the assumptions related to health-state utilities, the user have to specify in \textit{rmst.change} the expected relative change in terms of RMST between the two treatments. For instance, if the life expectancy of a patient with treatment B over the next 8 years (value entered in \textit{pro.time}) is 6.70 years, and assuming that the treatment A increases this life expectancy during the next 8 years by 1.33 years, the expected relative change in RMST is 0.20 ($=1.33/6.7$) (Royston and Parmar, 2011)

This is a single value if \textit{n.boot}=NULL, which corresponds to the estimated cut-off that maximizes the time-dependent expected utility of the medical decision. If this value corresponds to the minimum of the marker, all the patients should be treated with A. If this value corresponds to the maximum of the marker, all the patients should conserve the treatment B. When \textit{n.boot} is not null, two additional values are returned: \textit{ciInf} is the lower bound of the 95% confidence interval and \textit{ciSup} is the upper bound of the 95% confidence interval.

This value corresponds to the maximum expected utility associated with the estimation.

This data frame is composed by 8 columns representing respectively the cut-off values, the time-dependent expected utilities (utility), the proportions of patients with a marker value higher (\textit{pa}) and lower (\textit{pb}) than the cut-off value, the numbers of QALYs for patients with a marker value higher (\textit{qa}) and lower (\textit{qb}) than the cut-off value, the RMST for patients with a marker value higher (\textit{ea}) and lower (\textit{eb}) than the cut-off value.

This value represents the expected RMST for patients with a marker higher than the estimation (treated with A) minus the observed RMST for patients with a marker higher than the estimation(treated with B).
delta.qaly  This value represents the number of QALYs for patients with a marker higher than the estimation (treated with A) minus the observed number of QALYs for patients with a marker higher than the estimation (treated with B).

missing  Number of deleted observations due to missing data.

# the optimal cut-off: patients with an higher value should receive the treatment A

EUT.obj$estimation
**Description**

This function allows the estimation of an optimal cut-off for medical decision making between two treatments A and B from a prognostic marker by maximizing the expected utility in a time-dependent context.

**Usage**

EUT2(times, failures, variable, treatment, pro.time, u.A0, u.A1, u.B0, u.B1, n.boot)

**Arguments**

- **times**: A numeric vector with the follow up times.
- **failures**: A numeric vector with the event indicator (0=right censoring, 1=event).
- **variable**: A numeric vector with the observed values of the marker/variable under interest \( x \). This variable is collected at the baseline \( \text{times}=0 \). By convention, we assume that patients with \( x>k \) will preferentially receive A, \( k \) being the optimal cut-off. In contrast, patients with \( x<k \) will preferentially receive B.
- **treatment**: A character vector with the observed treatment. Only character strings "A" and "B" are allowed.
- **pro.time**: The prognostic time for which the capacities of the marker and the patient outcomes are considered in the same unit than the one used in the argument times.
- **u.A0**: A value of the utility of a patient receiving the treatment A before the event occurrence. This value should respect the 0-1 scale (from death to perfect health).
- **u.A1**: A value of the utility of a patient receiving the treatment A after the event occurrence. This value should respect the 0-1 scale.
- **u.B0**: A value of the utility of a patient receiving the treatment B before the event occurrence. This value should respect the 0-1 scale.
- **u.B1**: A value of the utility of a patient receiving the treatment B after the event occurrence. This value should respect the 0-1 scale.
- **n.boot**: Number of bootstrap iterations to compute the 95% confidence interval of the optimal cut-off. The default value is NULL: no confidence interval is estimated.

**Details**

This function computes the expected time-dependent utility for the cut-off values defined by the user. The data may be right-censored. The user has to define the utilities (qualities of life related to the possible health-states after the marker-based decision). A positive test is defined by a marker value higher than the cut-off \( x>k \): by convention the patient will receive preferentially the treatment A. A negative test is defined by a marker value lower than or equal to the cut-off \( x<k \): by
convention the patients will receive preferentially the treatment B. For example, the user has data from a clinical trial in which treatments A and B independently to the value of the marker X. She(he) assumes that an alternative treatment A will be more convenient for patients with high value of the marker X. She(he) aims to compute the optimal cut-off value for a future stratified medical decision rule: treatment A for patients with \( X \geq k \) and treatment B for patients with \( X < k \).

**Value**

- **estimation**: This is a single value if `n.boot=NULL`, which corresponds to the estimated cut-off that maximizes the time-dependent expected utility of the medical decision. If this value corresponds to the minimum of the marker, all the patients should be treated with A. If this value corresponds to the maximum of the marker, all the patients should conserve the treatment B. When `n.boot` is not null, two additional values are returned: \( CI_{inf} \) is the lower bound of the 95% confidence interval and \( CI_{sup} \) is the upper bound of the 95% confidence interval.

- **max.eu**: This value corresponds to the maximum expected utility associated with the estimation.

- **table**: This data frame is composed by 8 columns representing respectively the cut-off values (`cut.off`), the time-dependent expected utilities (`utility`), the proportions of patients with a marker value higher (`pa`) and lower (`pb`) than the cut-off value, the numbers of QALYs for patients with a marker value higher (`qa`) and lower (`qb`) than the cut-off value, the RMST for patients with a marker value higher (`ea`) and lower (`eb`) than the cut-off value.

- **delta.rmst**: This is a vector with two values. The first value, entitled `high.level`, represents the RMST for patients with a marker higher than the estimation and treated with A minus the RMST for patients with a marker higher than the estimation and treated with B. The second value, entitled `low.level`, represents the RMST for patients with a marker lower than or equal to the estimation and treated by B minus the RMST for patients with a marker lower than or equal to the estimation and treated with A.

- **delta.qaly**: This is a vector with two values. The first value, entitled `high.level`, represents the number of QALYs for patients with a marker higher than the estimation and treated by A minus the number of QALYs for patients with a marker higher than the estimation and treated with B. The second value, entitled `low.level`, represents the number of QALYs for patients with a marker lower than or equal to the estimation and treated with B minus the number of QALYs for patients with a marker lower than or equal to the estimation and treated with A.

- **missing**: Number of deleted observations due to missing data.

**fr.ratetable**

**Expected Mortality Rates Of The General French Population.**

**Description**

An object of class ratetable for the expected mortality of the French population. It is an array with three dimensions: age, sex and year.
Usage

data(fr.ratetable)

Format

The format is "ratetable". The attributes are:

- **dim**: A numeric vector with the length of each dimension.
- **dimnames**: A list of vectors with the names of each variable of the three dimensions.
- **dimid**: A character vector with the identification of the dimensions: age, year and sex.
- **factor**: A vector of indicators=1 if the corresponding dimension do not vary according to the time. Only the sex is associated to 1.
- **cutpoints**: A list of the thresholds to identify the mortality rates according to the time-varying dimensions (NULL for sex).
- **class**: The class of the object: ratetable.

Details

The organization of a ratetable object is described in details by Therneau (1999) and Pohar (2006).

Source

The original data and updates can be downloaded from the Human Life-Table Database (HMD, The Human Mortality Database). URL: http://www.mortality.org/

net.ROCt

*Net Time-Dependent ROC Curves With Right Censored Data.*

Description

This function performs the characteristics of a net time-dependent ROC curve (Lorent, 2013) based on k-nearest neighbor’s (knn) estimator or only based on the Pohar-Perme estimator (Pohar, 2012).
**net.ROCt**

**Usage**

```r
net.ROCt(times, failures, variable, p.age, p.sex, p.year, 
          rate.table, pro.time, cut.off, knn=FALSE, 
          prop=NULL)
```

**Arguments**

- `times` A numeric vector with the follow up times.
- `failures` A numeric vector with the event indicator (0=right censored, 1=event).
- `variable` A numeric vector with the prognostic variable. This variable is collected at the baseline.
- `p.age` A numeric vector with the age of the individuals at the baseline (in days).
- `p.sex` A character vector with the gender the individuals (‘male’ or ‘female’).
- `p.year` A numeric vector with the calendar year at the baseline (number of days from the January 1, 1960).
- `rate.table` A rate-table object with the expected mortality rates by age, sex, and cohort year. The same units used in `p.age`, `p.sex`, `p.year`.
- `pro.time` The value of prognostic time represents the maximum delay for which the capacity of the variable is evaluated. The same unit than the one used in the argument time.
- `cut.off` The cut-off values of the variable used to define the possible binary tests.
- `knn` A logical value indicating whether k-nearest neighbor’s estimator should be used.
- `prop` This is the proportion of the nearest neighbors. The estimation will be based on 2*prop (both right and left proportions) of the total sample size.

**Details**

This function computes net time-dependent ROC curve with right-censored data using estimator defined by Pohar-Perme et al. (2012) and the k-nearest neighbor’s (knn) estimator. The aim is to evaluate the capacity of a variable (measured at the baseline) to predict the excess of mortality of a studied population compared to the general population mortality. Using the knn estimator ensures a monotone and increasing ROC curve, but the computation time may be long. This approach may thus be avoided if the sample size is large because of computing time.

**Value**

- `table` This data frame presents the sensitivities and specificities associated with the cut-off values. One can observe NA if the value cannot be computed.
- `auc` The area under the time-dependent ROC curve for a prognostic up to prognostic time.
- `missing` Number of deleted observations due to missing data.
- `warning` This message indicates possible difficulties in the computation of the net ROC curve, for instance if the net survival was not lower or equal 1 to 1 for particular cut-off values or times.

Examples

```R
# import the observed data
data(dataDIVAT)

# A subgroup analysis to reduce the time needed for this example
dataDIVAT <- dataDIVAT[1:400,]

# import the expected mortality rates
data(fr.ratetable)

# the values of recipient age used for computing the sensibilities and specificities (choose more values in practice)
age.cut <- quantile(dataDIVAT$ageR, probs=seq(0.1, 0.9, by=0.1))

# recoding of the variables for matching with the ratetable
dataDIVAT$sex <- "male"
dataDIVAT$sex[dataDIVAT$sexR==0] <- "female"
dataDIVAT$year <- mdy.date(month=01, day=01, year=dataDIVAT$year.tx, nineteen = TRUE, fillday = FALSE, fillmonth = FALSE)
dataDIVAT$age <- dataDIVAT$ageR+365

# the ROC curve (without correction by the knn estimator) to reduce the time for computing this example. In practice, the correction should by used in case of non-montone results.
roc1 <- net.ROCt(times=dataDIVAT$death.time, failures=dataDIVAT$death, variable=dataDIVAT$ageR, p.age=dataDIVAT$age, p.sex=dataDIVAT$sex, p.year=dataDIVAT$year, rate.table=fr.ratetable, pro.time=3000, cut.off=age.cut, knn=FALSE)

# the sensibilities and specificities associated with the cut off values
roc1$table
```
# the traditional ROC graph

```r
plot(c(1, 1-roc$table$sp, 0), c(1, roc$table$se, 0), ylim=c(0, 1), xlim=c(0, 1),
     ylab="sensitivity", xlab="1-specificity", type="l", lty=1, col=2, lwd=2)

abline(c(0, 0), c(1, 1), lty=2)

legend("bottomright", paste("Without knn, (AUC=",
     round(roc$auc, 2), ")", sep=""), lty=1, lwd=2, col=2)
```

rein.ratetable | Expected Mortality Of French Patients With ESKD.

### Description

An object of the class rate-table which contains the expected mortality of French patients with End Stage Kidney Disease (ESKD) in dialysis and registered previously on waiting list for renal transplantation. It is an array with two dimensions: the time since the registry on waiting list and the patient profile at this baseline.

### Usage

```r
data(rein.ratetable)
```

### Format

The format is "ratetable". The attributes are:

- **dim**: A numeric vector with the length of each dimension.
- **dimnames**: A list of vectors with the names of each variable of both dimensions (see details for modalities of **profile**).
- **dimid**: A character vector with the identification of the dimensions: time, profile.
- **factor**: A vector of indicators=1 if the corresponding dimension do not vary according to the time.
  - The profile is associated to 1.
- **cutpoints**: A list of the thresholds to identify the mortality rates according to the time-varying dimensions (NULL for **profile**).
- **class**: The class of the object: ratetable.

### Details

The organization of a rate-table object is described in details by Therneau (1999) and Pohar (2006). We have estimated these data by using the renal epidemiology and information network (REIN). A competing risk model was performed in order to deal with the loss of follow-up to the transplantation. The profile represents the concatenation of the significant binary variables associated with the mortality on waiting list. In order to obtain the same variable in your database, we have to concatenate the following values in the same order. These values are collected at the registration date:
a. 1 if the patient is male and 0 if female.
b. 1 if the time between the first dialysis and the registration is higher than 1 year and 0 otherwise.
c. 1 if hemodialysis and 0 if peritoneal dialysis.
d. 1 if the patient is diabetic and 0 otherwise.
e. 1 if the patient had history of cardiac failure diabetic and 0 otherwise.
f. 1 if the patient had history of vascular failure diabetic and 0 otherwise.
g. 1 if the patient had history of cancer and 0 otherwise.
h. 1 if the age of the patients is in between 40 and 60 years and 0 otherwise.
i. 1 if the age of the patients is higher than 60 years and 0 otherwise.
j. 1 if the calendar year at registration is strictly higher than 2007 and 0
