Package ‘RODBC’

September 16, 2021

Version 1.3-19
Revision $Rev: 3553$
Date 2021-09-18
Title ODBC Database Access
Description An ODBC database interface.
SystemRequirements An ODBC3 driver manager and drivers.
Depends R (>= 4.0.0)
Imports stats
LazyLoad yes
Biarch yes
License GPL-2 | GPL-3
NeedsCompilation yes
Author Brian Ripley [aut, cre],
Maintainer Brian Ripley <ripley@stats.ox.ac.uk>

Package **RODBC** implements ODBC database connectivity.

See the package manual for details of installation and use. (This will show up as a vignette, and can be accessed via `RShowDoc("RODBC",package="RODBC")`.)

Two groups of functions are provided. The mainly internal `odbc*` commands implement low-level access to the ODBC functions of similar name. The `sql*` functions operate at a higher level to read, save, copy and manipulate data between data frames and SQL tables. Many connections can be open at once to any combination of DSN/hosts.

**Author(s)**

Michael Lapsley and Brian Ripley

---

**Description**

**Low-level ODBC functions**

R functions which talk directly to the ODBC interface.

**Usage**

```r
odbcTables(channel, catalog = NULL, schema = NULL, 
            tableName = NULL, tableType = NULL, literal = FALSE)
```

```r
odbcQuery(channel, query, rows_at_time = attr(channel, "rows_at_time"))
```

```r
odbcFetchRows(channel, max = 0, buffsize = 1000, 
               nullstring = NA_character_, believeNRows = TRUE)
```

```r
odbcGetErrMsg(channel)
```

```r
odbcClearError(channel)
```
Arguments

channel: connection handle as returned by `odbcConnect`, of class "RODBC".
catalog, schema, tableName, tableType: NULL or character: whether these do anything depends on the ODBC driver. The first three can be length-one character vectors, and `tableType` can specify zero or more types.
literal: logical: should arguments be interpreted literally or including wildcards?
query: any valid SQL statement.
rows_at_time: The number of rows to fetch at a time, between 1 and 1024. Not all drivers work correctly with values > 1: see `sqlQuery`.
max: limit on the number of rows to fetch, with 0 indicating no limit.
buffsize: the number of records to be transferred at a time.
nullstring: character string to be used when reading `SQL_NULL_DATA` items in a column transferred as character.
believeNRows: logical. Is the number of rows returned by the ODBC connection believable?

Details

These are low-level functions called by `sqlTables`, `sqlQuery`, `sqlGetResults` and similar high-level functions. They are likely to be confined to the `RODBC` namespace in the near future.

`odbcTables` enquires about the tables on the connected database. Whether arguments after the first do anything and what they do depends on the ODBC driver: see the help on `sqlTables` for some driver-specific details.

`odbcFetchRows` returns a data frame of the pending rowset, limited to `max` rows if `max` is greater than 0.

`buffsize` may be increased from the default of 1000 rows for increased performance on a large dataset. This only has an effect when `max` = 0 and `believeNRows` = FALSE (either for the ODBC connection or for this function call), in which case `buffsize` is used as the initial allocation length of the R vectors to hold the results. (Values of less than 100 are increased to 100.) If the initial size is too small the vector length is doubled, repeatedly if necessary.

Value

`odbcGetErrMsg` returns a (possibly zero-length) character vector of pending messages.
`odbcClearError` returns nothing, invisibly.

The others return 1 on success and -1 on failure, indicating that a message is waiting to be retrieved `odbcGetErrMsg`. `odbcFetchRows` may return -2 indicating "No Data", the message that would be returned by `odbcGetErrMsg`.

`sqlQuery`, `odbcConnect`, `odbcGetErrMsg`.
odbcClose

ODBC Close Connections

Description

Close connections to ODBC databases.

Usage

odbcClose(channel)

## S3 method for class 'RODBC'

close(con, ...)

odbcCloseAll()

Arguments

channel, con RODBC connection object as returned by odbcConnect.

... additional arguments passed from the generic.

Details

odbcClose cleans up and frees resources. It is also the method for the generic function close.

odbcCloseAll closes all open channels (amongst the first 1000 used in the session).

Channels are closed at the end of an R session, and may also be closed by garbage collection if no object refers to them. In both cases a warning is given (but may not be seen at the end of a console session).

Value

Function odbcClose returns a logical indicating if it succeeded, invisibly unless a warning is given.

The close method returns 0 (success) or 1, invisibly.

odbcConnect
odbcConnect  ODBC Open Connections

Description
Open connections to ODBC databases.

Usage
odbcConnect(dsn, uid = "", pwd = "", ...)

odbcDriverConnect(connection = "", case, believeNRows = TRUE,
  colQuote, tabQuote = colQuote,
  interpretDot = TRUE, DBMSencoding = "",
  rows_at_time = 100, readOnlyOptimize = FALSE)

odbcReConnect(channel, ...)

Arguments
dsn character string. A registered data source name.
uid, pwd UID and password for authentication (if required).
connection character string. See your ODBC documentation for the format.
... further arguments to be passed to odbcDriverConnect.
case Controls case changes for different DBMS engines. See ‘Details’.
channel RODBC connection object returned by odbcConnect.
believeNRows logical. Is the number of rows returned by the ODBC connection believable?
Not true for some Oracle and Sybase drivers, apparently, nor for Actual Technologies' SQLite driver for Mac OS X.
colQuote, tabQuote how to quote column (table) names in SQL statements. Can be of length 0
(no quoting), a length–1 character vector giving the quote character to be used
at both ends, or a length–2 character vector giving the beginning and ending
quotes. ANSI SQL uses double quotes, but the default mode for a MySQL
server is to use backticks.
The defaults are backtick ("\'") if the DBMS is identified as "MySQL" by the
driver, and double quote otherwise. A user reported that the SAS ODBC driver
required colQuote = NULL.
interpretDot logical. Should table names of the form qualifier.table be interpreted as table
table in schema qualifier (and for MySQL ‘schema’ means database)?
DBMSencoding character string naming the encoding returned by the DBMS. The default means
the encoding of the locale R is running under. Values other than the default re-
quire iconv to be available: it always is from R 2.10.0, otherwise see capabilities.
rods_at_time
The default number of rows to fetch at a time, between 1 and 1024. Not all drivers work correctly with values > 1: see sqlQuery.
readOnlyOptimize
logical: should the connection be optimized for read-only access?

Details
odbcConnect establishes a connection to the specified DSN, and odbcDriverConnect allows a more flexible specification via a connection string. odbcConnect uses the connection string "DSN=dsn;UID=uid;PWD=pwd",
omitting the last two components if they are empty.
For DBMSs that translate table and column names case must be set appropriately. Allowable values are "nochange", "toupper" and "tolower" as well as the names of databases where the behaviour is known to us (currently "mysql", which maps to lower case on Windows but not on Linux, "postgresql" (lower), and "msaccess" (nochange)). If case is not specified, the default is "nochange" unless the appropriate value can be figured out from the DBMS name reported by the ODBC driver. It is likely that "toupper" is desirable on IBM’s DB2, but this is not enforced.
Note that readOnlyOptimize may do nothing, and is not guaranteed to enforce read-only access. With drivers that support it, it is used to optimize locking strategies, transaction management and so on. It does make access to Mimer read-only, and has no effect on MySQL.
Function odbcReConnect re-connects to a database using the settings of an existing (and presumably now closed) channel object. Arguments given in the original call can be overridden as needed.
Note that if a password is supplied (either as a pwd argument or as part of the DSN) it may be stored in the connection.string element of the return value, but the value is (from RODBC 1.3-0) replaced by ******. (This will break odbcReConnect.)
If it is possible to set the DBMS or ODBC driver to communicate in the character set of the R session then this should be done. For example, MySQL can set the communication character set via SQL, e.g. ‘SET NAMES ’utf8’’.

Value
A non-negative integer which is used as handle if no error occurred, -1 otherwise. A successful return has class "RODBC", and attributes including
connection.string
the full ODBC connection string.
        case
the value of case.
        id
a numeric ID for the channel.
believeNRows
the value of believeNRows.
        rows_at_time
the value of rows_at_time.

Note
Several errors which have been reported as bugs in RODBC 1.3-0 which were in fact ODBC driver errors that can be circumvented by setting rows_at_time = 1 (and the warning under that argument has always been there). The drivers involved have been third-party Oracle drivers and old SQL Server drivers.
odbcDataSources

Examples

## Not run:
# MySQL
channel <- odbcConnect("test", uid="ripley", pwd="secret")
# PostgreSQL: 'case' should be detected automatically
channel <- odbcConnect("pg", uid="ripley", pwd="secret", case="postgresql")

# re-connection
odbcCloseAll()
channel <- odbcReConnect(channel) # must re-assign as the data may change

## End(Not run)

---

odbcDataSources        List ODBC Data Sources

Description

List known ODBC data sources.

Usage

odbcDataSources(type = c("all", "user", "system"))

Arguments

type        User DSNs, system DSNs or all?

Value

A named character vector of DSN descriptions, with names the DSNs.

Author(s)

Brian Ripley
odbcGetInfo

Request Information on an ODBC Connection

Description

Request information on an ODBC connection.

Usage

odbcGetInfo(channel)

Arguments

channel connection handle as returned by odbcConnect of class "RODBC".

Value

A named character string giving information on the database and ODBC driver in use on the connection channel.

Author(s)

Brian Ripley
odbcSetAutoCommit

### ODBC Set Auto-Commit Mode

**Description**

Set ODBC database connection's auto-commit mode.

**Usage**

```r
odbcSetAutoCommit(channel, autoCommit = TRUE)
```

```r
odbcEndTran(channel, commit = TRUE)
```

**Arguments**

- `channel`: RODBC connection object returned by `odbcConnect`.
- `autoCommit`: logical. Set auto-commit on?
- `commit`: logical. Commit or rollback pending transaction?
setSqlTypeInfo

Details

Auto-commit is a concept supported only by ODBC connections to transactional DBMSs.

If a connection to a transactional DBMS is in auto-commit mode (the default), then all its SQL statements will be executed and committed as individual transactions. Otherwise, its SQL statements are grouped into transactions that are terminated by an execution of commit or rollback. Switching a connection to auto-commit mode commits the pending transaction.

By default, new connections are in auto-commit mode. If auto-commit mode has been disabled, a call to odbcEndTran or an SQL commit statement must be executed in order to commit changes; otherwise, pending database changes will not be saved.

Value

odbcSetAutoCommit stops if channel is an invalid connection. The function returns -1 on error, 0 on success and on success with a message that would be returned by odbcGetErrMsg.

Author(s)

Norman Yamada, Yasser El-Zein

Description

Specify or Query a Mapping of R Types to DBMS Types

Usage

setSqlTypeInfo(driver, value)

getSqlTypeInfo(driver)

Arguments

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>driver</td>
<td>A character string specifying the DBMS name as returned by odbcGetInfo. Optional for getSqlTypeInfo.</td>
</tr>
<tr>
<td>value</td>
<td>A named list with character values. This should have names &quot;double&quot;, &quot;integer&quot;, &quot;character&quot; and &quot;logical&quot;, and values SQL types appropriate to the DBMS.</td>
</tr>
</tbody>
</table>

Details

This information is used by sqlSave if it creates a table in the DBMS and is not overridden by arguments typeId or varTypes. Mappings are included for MySQL, PostgreSQL, SQLite, Oracle, Mimer, DB2 on Windows, and the Microsoft SQL Server, Access, Excel and Dbase drivers.

The SQL types chosen should be nullable to allow NAs to be represented. (Bit and boolean types often are not.)
sqlColumns

Description
Enquire about the column structure of tables on an ODBC database connection.

Usage

sqlColumns(channel, sqtable, errors = FALSE, as.is = TRUE,
            special = FALSE, catalog = NULL, schema = NULL,
            literal = FALSE)

sqlPrimaryKeys(channel, sqtable, errors = FALSE, as.is = TRUE,
                catalog = NULL, schema = NULL)

Arguments

channel: connection object as returned by odbcConnect.
sqtable: character string: a database table (or view or similar) name accessible from the connected DSN. If wildcards are allowed (only for sqlColumns(special=FALSE)), results for all matching tables.
errors: logical: if true halt and display error, else return -1.
as.is: see sqlGetResults.
sqlColumns

**special**  logical. If true, return only the column(s) needed to specify a row uniquely. Depending on the database, there might be none.

catalog, schema  NULL or character: additional information on where to locate the table: see `sqlTables` for driver-specific details. Wildcards may be supported in schema for `sqlColumns(special=FALSE)`.

**literal**  logical: wildcards may be interpreted in schema and `sqtable`: if so this may suppress such interpretation.

### Details

The argument `special = TRUE` to `sqlColumns` returns the column(s) needed to specify a row uniquely. This is intended to form the basis of an SQL WHERE clause for update queries (see `sqlUpdate`), and what (if anything) it does is DBMS-specific. On many DBMSs it will return the primary keys if present: on others it will return a pseudo-column such as `ROWID` (Oracle) or `_ROWID_` (SQLite), either always (Oracle) or if there is no primary key.

Primary keys are implemented in some DBMSs and drivers. A table can have a single column designated as a primary key or, in some cases, multiple columns. Primary keys should not be nullable (that is, cannot contain missing values). They can be specified as part of a ‘CREATE TABLE’ statement or added by a ‘ALTER TABLE’ statement.

In principle specifying `catalog` should select an alternative database in MySQL or an attached database in SQLite, but neither works with current drivers.

If `sqtable` contains ‘.’ and neither `catalog` nor `schema` is supplied, an attempt is made to interpret `qualifier.table` as table `table` in schema `qualifier` (and for MySQL ‘schema’ means ‘database’, but the current drivers fail to interpret `catalog=` so this does not yet work). (This can be suppressed by opening the connection with `interpretDot = FALSE`). This has been tested successfully on PostgreSQL, SQL Server, Oracle, DB2 and Mimer.

Whether wildcards are accepted for `sqtable` and `schema` in `sqlColumns(special = FALSE)` depends on the driver and may be changed by the value of literal. For example, the PostgreSQL driver tested allowed wildcards in `schema` only if `literal = FALSE` and never in `sqtable`, whereas two MySQL drivers both failed to match a database when `catalog` was supplied and always allowed wildcards in `sqtable` even if `literal = TRUE`.

### Value

A data frame on success. If no data is returned, either a zero-row data frame or an error. (For example, if there are no primary keys or special column(s) in this table an empty data frame is returned, but if primary keys are not supported by the ODBC driver or DBMS, an error code results.) The column names are not constant across ODBC versions so the data should be accessed by column number.

For `sqlPrimaryKeys` and `sqlColumns(special=FALSE)` the first four columns give the catalog, schema, table and column names (where applicable). For `sqlPrimaryKeys` the next two columns are the column sequence number (starting with 1) and name of the primary key: drivers can define further columns. For `sqlColumns(special=FALSE)` there are 18 columns: see https://docs.microsoft.com/en-us/sql/odbc/reference/syntax/sqlcolumns-function?view=sql-server-ver15.

Those beyond the first 6 shown in the examples give the ‘ordinal position’ (column 17) and further characteristics of the column type: see `sqlTypeInfo`. 
For the numeric values returned by `sqlColumns(special=TRUE)` see https://docs.microsoft.com/en-us/sql/odbc/reference/syntax/sqlspecialcolumns-function?view=sql-server-ver15: the scope should always be 2 (the session) since that is the scope requested in the call. For the `PSEUDO_COLUMN` column, the possible values are 0 (unknown), 1 (no) and 2 (yes).

1 <NA> <NA> USArrests rownames 1 PRIMARY
> sqlDrop(channel, "USArrests")
> close(channel)

## End(Not run)
```

---

## sqlCopy

**ODBC Copy**

**Description**

Functions to copy tables or result sets from one database to another.
Usage

sqlCopy(channel, query, destination, destchannel = channel,
    verbose = FALSE, errors = TRUE, ...)

sqlCopyTable(channel, srctable, desttable, destchannel = channel,
    verbose = FALSE, errors = TRUE)

Arguments

channel, destchannel
    connection handle as returned by odbcConnect.
query
    any valid SQL statement
destination, srctable, desttable
    character: a database table name accessible from the connected DSN.
verbose
    Display statements as they are sent to the server?
errors
    if TRUE halt and display error, else return -1.
... additional arguments to be passed to sqlSave.

Details

sqlCopy as is like sqlQuery, but saves the output of query in table destination on channel destchannel.
sqlCopyTable copies the structure of srctable to desttable on DSN destchannel. This is within the limitations of the ODBC lowest common denominator. More precise control is possible via sqlQuery.

Value

See sqlGetResults.

Author(s)

Michael Lapsley and Brian Ripley

See Also

sqlQuery, sqlSave

Examples

## Not run: ## example for a l/casing DBMS
sqlSave(channel, USArrests, rownames = "state")
query <- paste("select state, murder from usarrests",
    "where rape > 30", "order by murder")
sqlCopy(channel, query, "HighRape", rownames = FALSE)
sqlFetch(channel, "HighRape", rownames = "state", max = 5)
sqlDrop(channel, "HighRape")

## End(Not run)
Description

`sqlClear` deletes all the rows of the table `sqtable`.
`sqlDrop` removes the table `sqtable` (if permitted).

Usage

```r
sqlClear(channel, sqtable, errors = TRUE)
sqlDrop(channel, sqtable, errors = TRUE)
```

Arguments

- `channel`: connection object as returned by `odbcConnect`.
- `sqtable`: character string: a database table name accessible from the connected DSN. This can be a ‘dotted’ name of the form `schema.table`.
- `errors`: logical: if TRUE halt and display error, else return -1.

Details

These submit ‘TRUNCATE TABLE’ and ‘DROP TABLE’ SQL queries respectively.
‘Dotted’ table names are allowed on systems that support them but the existence of the table is not checked and so attempting these operations on a non-existent table will give a low-level error. (This can be suppressed by opening the connection with `interpretDot = FALSE`.)
The default ‘drop’ behaviour in Oracle is to move the table to the ‘recycle bin’: use

```r
sqlQuery(channel, "PURGE recyclebin")
```
to empty the recycle bin.
The current user might not have privileges to allow these operations, and Actual Technologies’ Mac OS X SQLite driver has a bug causing them silently to fail.

Value

If `errors = FALSE`, a numeric value, invisibly. Otherwise a character string or `invisible()`.

`odbcConnect, sqlQuery, sqlFetch, sqlSave, sqlTables, odbcGetInfo`
sqlFetch  

Reading Tables from ODBC Databases

Description

Read some or all of a table from an ODBC database into a data frame.

Usage

sqlFetch(channel, sqtable, ..., colnames = FALSE, rownames = TRUE)

sqlFetchMore(channel, ..., colnames = FALSE, rownames = TRUE)

Arguments

channel  
connection handle returned by odbcConnect.

sqtable  
a database table name accessible from the connected DSN. This should be either a literal character string or a character vector of length 1.

...  
additional arguments to be passed to sqlQuery or sqlGetResults. See ‘Details’.

colnames  
logical: retrieve column names from first row of table? (For use when sqlSave(colnames = TRUE) was used.)

rownames  
either logical or character. If logical, retrieve row names from the first column (rownames) in the table? If character, the column name to retrieve them from.

Details

Note the ‘table’ includes whatever table-like objects are provided by the DBMS, in particular views and system tables.

sqlFetch by default retrieves the the entire contents of the table sqtable. Rownames and column names are restored as indicated (assuming that they have been placed in the table by the corresponding arguments to sqlSave).

Alternatively, sqlFetch can fetch the first max rows, in which case sqlFetchMore will retrieve further result rows, provided there has been no other ODBC query on that channel in the meantime.

These functions try to cope with the peculiar way the Excel ODBC driver handles table names, and to quote Access table names which contain spaces. Dotted table names, e.g. myschema.mytable, are allowed on systems that support them, unless the connection was opened with interpretDot = FALSE.

Useful additional parameters to pass to sqlQuery or sqlGetResults include

max: limit on the number of rows to fetch, with 0 (the default) indicating no limit.

nullstring: character string to be used when reading SQL_NULL_DATA character items from the database: default NA_character_.

na.strings: character string(s) to be mapped to NA when reading character data: default "NA".
as.is: as in `sqlGetResults`.

dec: The character for the decimal place to be assumed when converting character columns to numeric.

rows_at_time: Allow for multiple rows to be retrieved at once. See `sqlQuery`.

Value

A data frame on success, or a character or numeric error code (see `sqlQuery`).

Note

If the table name desired is not a valid SQL name (alphanumeric plus _) and these functions are not able to interpret the name, you can use `sqlQuery` with whatever quoting mechanism your DBMS vendor provides (e.g. [ ] on some Microsoft products and backticks on MySQL).

Author(s)

Michael Lapsley and Brian Ripley

See Also

`sqlSave`, `sqlQuery`, `odbcConnect`, `odbcGetInfo`

Examples

```r
## Not run:
channel <- odbcConnect("test")
sqlSave(channel, USArrests)
sqlFetch(channel, "USArrests") # get the lot
sqlFetch(channel, "USArrests", max = 20, rows_at_time = 10)
sqlFetchMore(channel, max = 20)
sqlFetchMore(channel) # get the rest
sqlDrop(channel, "USArrests")
close(channel)

## End(Not run)
```
Usage

sqlQuery(channel, query, errors = TRUE, ..., rows_at_time)

sqlGetResults(channel, as.is = FALSE, errors = FALSE,
               max = 0, buffsize = 1000,
               nullstring = NA_character_, na.strings = "NA",
               believeNRows = TRUE, dec = getOption("dec"),
               stringsAsFactors = FALSE)

Arguments

channel  connection handle as returned by odbcConnect.
query    any valid SQL statement.
errors   logical: if true halt and display error, else return -1.
...      additional arguments to be passed to sqlGetResults.
rows_at_time The number of rows to fetch at a time, between 1 and 1024. See ‘Details’.
as.is    which (if any) columns returned as character should be converted to another type? Allowed values are as for read.table. See ‘Details’.
max      limit on the number of rows to fetch, with 0 indicating no limit.
buffsize an initial guess at the number of rows, used if max = 0 and believeNRows == FALSE.
nullstring character string to be used when reading SQL_NULL_DATA character items from the database.
a.strings character vector of strings to be mapped to NA when reading character data.
believeNRows logical. Is the number of rows returned by the ODBC connection believable? This might have been set to false when the channel was opened, and if so that setting cannot be overridden.
decklarge The character for the decimal place to be assumed when converting character columns to numeric.
stringsAsFactors logical: should columns returned as character and not excluded by as.is and not converted to anything else be converted to factors?

Details

sqlQuery is the workhorse function of RODBC. It sends the SQL statement query to the server, using connection channel returned by odbcConnect, and retrieves (some or all of) the results via sqlGetResults.

The term ‘query’ includes any valid SQL statement including table creation, alteration, updates etc as well as ‘SELECT’s. The sqlQuery command is a convenience wrapper that first calls odbcQuery and then sqlGetResults. If finer-grained control is needed, for example over the number of rows fetched, additional arguments can be passed to sqlQuery or the underlying functions called directly.

sqlGetResults is a mid-level function. It is called after a call to sqlQuery or odbcQuery to retrieve waiting results into a data frame. Its main use is with max set to non-zero when it will
retrieve the result set in batches with repeated calls. This is useful for very large result sets which can be subjected to intermediate processing.

Where possible sqlGetResults transfers data in binary form: this happens for columns of (ODBC) SQL types double, real, integer and smallint, and for binary SQL types (which are transferred as lists of raw vectors, given class "ODBC_binary"). All other SQL data types are converted to character strings by the ODBC interface.

This paragraph applies only to SQL data types which are returned by ODBC as character vectors. If when creating the connection (see odbcConnect) DBMSencoding was set to a non-empty value, the character strings are re-encoded. Then if as.is is true for a column, it is returned as a character vector. Otherwise (where detected) date, datetime and timestamp values are converted to the "Date" or "POSIXct" class. (Some drivers seem to confuse times with dates, so times may get converted too. Also, some DBMSs (e.g. Oracle’s) idea of date is a date-time.) Remaining cases are converted by R using type.convert. When character data are to be converted to numeric data, the setting of options("dec") is used to map the character used by the ODBC driver in setting decimal points—this is set to a locale-specific value when RODBC is initialized if it is not already set.

Using buffsize will yield a marginal increase in speed if set to no less than the maximum number of rows when believeNRows = FALSE. (If set too small it can result in unnecessarily high memory use as the buffers will need to be expanded.)

Using buffsize will yield a marginal increase in speed if set to no less than the maximum number of rows when believeNRows = FALSE. (If set too small it can result in unnecessarily high memory use as the buffers will need to be expanded.)

Modern drivers should work (and work faster, especially if communicating with a remote machine) with rows_at_time = 100, the usual default, or more. (However, some drivers may mis-fetch multiple rows, in which case set rows_at_time = 1 when creating the connection.) However, if max is specified then this may fetch too many rows and hence it could be reduced (but then this setting applies to all subsequent fetches from that result set). Another circumstance in which you might want to reduce rows_at_time is if there are large character columns in the result set: with the default value up to 6Mb of buffer for each such column could be allocated to store intermediate results.

Value

On success, a data frame (possibly with 0 rows) or character string. On error, if errors = TRUE a character vector of error message(s), otherwise an invisible integer error code -1 (general, call odbcGetErrMsg for details) or -2 (no data, which may not be an error as some SQL statements do return no data).

### sqlSave

Write a Data Frame to a Table in an ODBC Database

**Description**

Write or update a table in an ODBC database.

**Usage**

```r
sqlSave(channel, dat, tablename = NULL, append = FALSE,  
         rownames = TRUE, colnames = FALSE, verbose = FALSE,  
         safer = TRUE, addPK = FALSE, typeInfo, varTypes,  
         fast = TRUE, test = FALSE, nastring = NULL)
```

```r
sqlUpdate(channel, dat, tablename = NULL, index = NULL,  
          verbose = FALSE, test = FALSE, nastring = NULL,  
          fast = TRUE)
```

**Arguments**

- `channel`: connection handle returned by `odbcConnect`.
- `dat`: a data frame.
- `tablename`: character: a database table name accessible from the connected DSN. If missing, the name of `dat`.
- `index`: character. Name(s) of index column(s) to be used.
- `append`: logical. Should data be appended to an existing table?
- `rownames`: either logical or character. If logical, save the row names as the first column rownames in the table? If character, the column name under which to save the rownames.
- `colnames`: logical: save column names as the first row of table?
- `verbose`: display statements as they are sent to the server?
- `safer`: logical. If true, create a non-existing table but only allow appends to an existing table. If false, allow `sqlSave` to attempt to delete all the rows of an existing table, or to drop it.
- `addPK`: logical. Should rownames (if included) be specified as a primary key?
- `typeInfo`: optional list of DBMS datatypes. Should have elements named “character”, “double” and “integer”.
### Parameter Descriptions

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>varTypes</code></td>
<td>an optional named character vector giving the DBMSs datatypes to be used for some (or all) of the columns if a table is to be created.</td>
</tr>
<tr>
<td><code>fast</code></td>
<td>logical. If false, write data a row at a time. If true, use a parametrized INSERT INTO or UPDATE query to write all the data in one operation.</td>
</tr>
<tr>
<td><code>test</code></td>
<td>logical: if TRUE show what would be done, only.</td>
</tr>
<tr>
<td><code>nastring</code></td>
<td>optional character string to be used for writing NAs to the database. See ‘Details’.</td>
</tr>
</tbody>
</table>

### Details

`sqlSave` saves the data frame `dat` in the table `tablename`. If the table exists and has the appropriate structure it is used, or else it is created anew. If a new table is created, column names are remapped by removing any characters which are not alphanumeric or _, and the types are selected by consulting arguments `varTypes` and `typeInfo`, then looking the driver up in the database used by `getSqlTypeInfo` or failing that by interrogating `sqlTypeInfo`.

If `rownames = TRUE` the first column of the table will be the row labels with `colname rowname`: `rownames` can also be a string giving the desired column name (see ‘Examples’). If `colnames` is true, the column names are copied into row 1. This is intended for cases where case conversion alters the original column names and it is desired that they are retained. Note that there are drawbacks to this approach: it presupposes that the rows will be returned in the correct order; not always valid. It will also cause numeric columns to be returned as factors.

Argument `addPK = TRUE` causes the row names to be marked as a primary key. This is usually a good idea, and may allow database updates to be done. However, the ODBC drivers for some DBMSs (e.g. Access) do not support primary keys, and earlier versions of the PostgreSQL ODBC driver generated internal memory corruption if this option is used.

`sqlUpdate` updates the table where the rows already exist. Data frame `dat` should contain columns with names that map to (some of) the columns in the table. It also needs to contain the column(s) specified by `index` which together identify the rows to be updated. If `index = NULL`, the function tries to identify such columns. First it looks for a primary key for the table, then for the column(s) that the database regards as the optimal for defining a row uniquely (these are returned by `sqlColumns(special = TRUE)` if this returns a pseudo-column it cannot be used as we do not have values for the rows to be changed). Finally, the row names are used if they are stored as column "rownames" in the table.

When `fast = TRUE`, NAs are always written as SQL nulls in the database, and this is also the case if `fast = FALSE` and `nastring = NULL` (its default value). Otherwise `nastring` gives the character string to be sent to the driver when NAs are encountered: for all but the simplest applications it will be better to prepare a data frame with non-null missing values already substituted.

If `fast = FALSE` all data are sent as character strings. If `fast = TRUE`, integer and double vectors are sent as types `SQL_C_SLONG` and `SQL_C_DOUBLE` respectively. Some drivers seem to require `fast = FALSE` to send other types, e.g. datetime. SQLite’s approach is to use the data to determine how it is stored, and this does not work well with `fast = TRUE`.

If `tablename` contains ‘.’ and neither `catalog` nor `schema` is supplied, an attempt is made to interpret `qualifier.table` names as table `table` in schema `qualifier` (and for MySQL ‘schema’ means ‘database’). (This can be suppressed by opening the connection with `interpretDot = FALSE`.)

### Value

1 invisibly for success (and failures cause errors).
Warning

sqlSave(safer = FALSE) uses the ‘great white shark’ method of testing tables (bite it and see). The logic will unceremoniously DROP the table and create it anew with its own choice of column types in its attempt to find a writable solution. test = TRUE will not necessarily predict this behaviour. Attempting to write indexed columns or writing to pseudo-columns are less obvious causes of failed writes followed by a DROP. If your table structure is precious it is up to you back it up.

Examples

## Not run:
channel <- odbcConnect("test")
sqlSave(channel, USArrests, rownames = "state", addPK=TRUE)
sqlFetch(channel, "USArrests", rownames = "state") # get the lot
foo <- cbind(state=row.names(USArrests), USArrests)[1:3, c(1,3)]
foo[1,2] <- 222
sqlUpdate(channel, foo, "USArrests")
sqlFetch(channel, "USArrests", rownames = "state", max = 5)
sqlDrop(channel, "USArrests")
close(channel)

## End(Not run)
sqlTables

Arguments

channel  
connection handle as returned by odbcConnect.

errors  
if TRUE halt and display error, else return -1.

as.is  
as in sqlGetResults.

catalog, schema, tableName, tableType  
NULL or character: whether these do anything depends on the ODBC driver. The first three can be length-one character vectors, and tableType can specify zero or more types in separate elements of a character vector.

literal  
logical: (where supported) should arguments be interpreted literally or including wildcards?

Value

A data frame on success, or character/numeric on error depending on the errors argument. (Use sqlGetResults for further details of errors.)

The column names depend on the database, containing a third column TABLE_NAME (not always in upper case): however, they are supposed to be always in the same order.

The first column is the ‘catalog’ or (in ODBC2 parlance) ‘qualifier’, the second the ‘schema’ or (ODBC2) ‘owner’, the third the name, the fourth the table type (one of "TABLE", "VIEW", "SYSTEM TABLE", "ALIAS", "SYNONYM", or a driver-specific type name) and the fifth column any remarks.

Oddly, the Microsoft Excel driver considers worksheets to be system tables, and named ranges to be tables.

Driver-specific details

Whether the additional arguments are implemented and what they do is driver-specific. The standard SQL wildcards are underscore to match a single character and percent to match zero or more characters (and often backslash will escape these): these are not used for table types. All of these drivers interpret wildcards in tableName, and in catalog or schema where supported.

Setting one of catalog or schema to "%" and the other and tableName to "" should give a list of available catalogs or schemas, whereas

    catalog = "", schema = "", tableName = "", tableType = "%"

should list the supported table types.

For MySQL, catalog refers to a database whereas schema is mostly ignored, and literal is ignored. To list all databases use just catalog = "%". In the 5.1.x driver, use catalog="db_name",tableName="%" to list the tables in another database, and to list the table types use the form displayed above.

For PostgreSQL's ODBC driver catalog is ignored (except that catalog = "" is required when listing schema or table types) and literal works for both schema and for tableName.

SQLite ODBC ignores catalog and schema, except that the displayed form is used to list table types. So although it is possible to attach databases and to refer to them by the dotted name notation, it is apparently impossible to list tables on attached databases.
Microsoft SQL Server 2008 interprets both catalog and schema. With literal = TRUE it only finds tables if schema is set (even to an empty string). Schemas are only listed if they contain objects.

Oracle’s Windows ODBC driver finds no matches if anything non-empty is supplied for the catalog argument. Unless a schema is specified it lists tables in all schemas. It lists available table types as just "TABLE" and "VIEW", but other types appear in listings. With literal = TRUE it only finds tables if schema is set (even to an empty string).

DB2 implements schemas but not catalogs. literal = TRUE has no effect. In some uses case matters and upper-case names must be used for schemas.

The Microsoft Access and Excel drivers interpret catalog as the name of the Access .mdb or Excel .xls file (with the path but without the extension): wildcards are interpreted in catalog (for files in the same folder as the attached database) and tableName. Using schema is an error except when listing catalogs or table types. The Excel driver matched tableType = "TABLE" (a named range) but not tableType = "SYSTEM TABLE" (the type returned for worksheets).

The Actual Technologies Access/Excel driver ignores all the additional arguments.

## End(Not run)
sqlTypeInfo

Request Information about Data Types in an ODBC Database

Description

Request information about data types in an ODBC database

Usage

sqlTypeInfo(channel, type = "all", errors = TRUE, as.is = TRUE)

Arguments

channel
connection handle as returned by odbcConnect.

type
The types of columns about which information is requested. Possible values are "all", "char", "varchar", "wchar", "wvarchar" (Unicode), "real", "float", "double", "integer", "smallint", "date", "time", "timestamp", "binary", "varbinary", "longvarbinary" and (its alias) "blob".

ersrors
logical: if true halt and display error, else return -1.

as.is
as in sqlGetResults.

Details

sqlTypeInfo attempts to find the types of columns the database supports: ODBC drivers are not required to support this (but all known examples do). Where it is supported, it is used by sqlSave to decide what column types to create when creating a new table in the database.

Value

A data frame on success, or character/numeric on error depending on the errors argument. Use sqlGetResults for further details of errors.

The columns returned may depend on the ODBC driver manager. For a fully ODBC 3 manager, see https://docs.microsoft.com/en-us/sql/odbc/reference/syntax/sqlgettypeinfo-function?view=sql-server-ver15

the symbolic constants mentioned there will be returned as numbers (and the values of the numeric constants can be found in the ODBC headers such as `sql.h` and `sqlext.h`).
