Package ‘RcppAlgos’

December 10, 2023

Version 2.8.3

Title High Performance Tools for Combinatorics and Computational Mathematics

Description Provides optimized functions and flexible combinatorial iterators implemented in C++ for solving problems in combinatorics and computational mathematics. Utilizes the RMatrix class from 'RcppParallel' for thread safety. There are combination/permutation functions with constraint parameters that allow for generation of all results of a vector meeting specific criteria (e.g. generating integer partitions/compositions or finding all combinations such that the sum is between two bounds). Capable of generating specific combinations/permutations (e.g. retrieve only the nth lexicographical result) which sets up nicely for parallelization as well as random sampling. Gmp support permits exploration where the total number of results is large (e.g. comboSample(10000, 500, n = 4)). Additionally, there are several high performance number theoretic functions that are useful for problems common in computational mathematics. Some of these functions make use of the fast integer division library 'libdivide'. The primeSieve function is based on the segmented sieve of Eratosthenes implementation by Kim Walisch. It is also efficient for large numbers by using the cache friendly improvements originally developed by Tomás Oliveira. Finally, there is a prime counting function that implements Legendre's formula based on the work of Kim Walisch.

Description
The RcppAlgos package attacks age-old problems in combinatorics and computational mathematics.

Goals
1. The main goal is to encourage fresh and creative approaches to foundational problems. The question that most appropriately summarizes RcppAlgos is: "Can we do better?".
2. Provide highly optimized functions that facilitates a broader spectrum of researchable cases. E.g.
   - Investigating the structure of large numbers over wide ranges:
     - primeFactorizeSieve(10^13 - 10^7, 10^13 + 10^7)
     - primeSieve(2^53 - 10^10, 2^53 - 1, nThreads = 32)
   - Easily explore combinations/permutations/partitions that would otherwise be inaccessible due to time of execution/memory constraints:
     - c_iter = comboIter(10000, 100)
       bigSamp = gmp::urand.bigz(3, gmp::log2.bigz(comboCount(10000, 100)))
       c_iter[[bigSamp]] ## flexible iterator allows random sampling
     - p_iter = partitionsIter(5000, 100, target = 6000)
       p_iter[[1e9]] ## start iterating from index = 1e9
       p_iter@nextIter()
       p_iter@nextNIter(1e3)
     - comboGeneral(150, 5, constraintFun = "sum", Parallel = TRUE)
     - parallel::mclapply(seq(...), function(x) {
       temp = permuteGeneral(15, 10, lower = x, upper = y)
       ## analyze permutations
       ## output results
     }, mc.cores = detectCores() - 1))
     - partitionsGeneral(0:80, repetition = TRUE)
     - permuteSample(rnorm(100), 10, freqs = rep(1:4, 25), n = 15, seed = 123)
     - set.seed(123)
       comboGeneral(runif(42, 0, 50), 10,
       constraintFun = "mean",
       comparisonFun = c(">","<"),
       limitConstraints = c(39.876, 42.123))
3. Speed!!!... You will find that the functions in RcppAlgos are some of the fastest of their type available in R.
Description

The Combo class family are S4-classes that expose C++ classes that provide access to iterators and other useful methods.

Slots

of "Combo" and all classes inheriting from it:

nextIter  Retrieve the next lexicographical result
nextNIter  Pass an integer $n$ to retrieve the next $n$ lexicographical results
nextRemaining  Retrieve all remaining lexicographical results
currIter  Returns the current iteration
prevIter  Retrieve the previous lexicographical result (the next reverse lexicographical result)
prevNIter  Pass an integer $n$ to retrieve the previous $n$ lexicographical results (the next $n$ reverse lexicographical results)
prevRemaining  Retrieve all remaining reverse lexicographical results
startOver  Resets the iterator
sourceVector  View the source vector
summary  Returns a list of summary information about the iterator
front  Retrieve the first lexicographical result
back  Retrieve the last lexicographical result
randomAccess  Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.

Examples

showClass("Combo")
Description

Calculate the number of combinations/permutations of a vector chosen \( m \) at a time with or without replacement. Additionally, these functions can calculate the number of combinations/permutations of multisets.

Usage

```r
comboCount(v, m = NULL, ...)  
permuteCount(v, m = NULL, ...)
```

## Default S3 method:
```r
comboCount(v, m = NULL, repetition = FALSE, freqs = NULL, ...)
## Default S3 method:
permuteCount(v, m = NULL, repetition = FALSE, freqs = NULL, ...)
```

## S3 method for class 'table'
```r
comboCount(v, m = NULL, ...)
## S3 method for class 'table'
permuteCount(v, m = NULL, ...)
```

Arguments

- **v**
  - Source vector. If \( v \) is a positive integer, it will be converted to the sequence \( 1:v \). If \( v \) is a negative integer, it will be converted to the sequence \( v:-1 \). All atomic types are supported (See `is.atomic`).

- **m**
  - Number of elements to choose. If \( \text{repetition} = \text{TRUE} \) or \( \text{freqs} \) is utilized, \( m \) can exceed the length of \( v \). If \( m = \text{NULL} \), the length will default to \( \text{length}(v) \) or \( \text{sum}(\text{freqs}) \).

- **...**
  - Further arguments passed to methods.

- **repetition**
  - Logical value indicating whether combinations/permutations should be with or without repetition. The default is \( \text{FALSE} \).

- **freqs**
  - A vector of frequencies used for producing all combinations/permutations of a multiset of \( v \). Each element of \( \text{freqs} \) represents how many times each element of the source vector, \( v \), is repeated. It is analogous to the \( \text{times} \) argument in `rep`. The default value is \( \text{NULL} \).

Value

A numerical value representing the total number of combinations/permutations.

Note

When the number of results exceeds \( 2^{53} - 1 \), a number of class \texttt{bigz} is returned.
See Also
comboGeneral, permuteGeneral

Examples

```r
## Same interface as the respective "general" functions:
## i.e. comboGeneral & permuteGeneral

permuteCount(-5)
permuteCount(5)
comboCount(25, 12)
permuteCount(15, 7, TRUE)
comboCount(25, 12, freqs = rep(2, 25))

## Return object of class 'bigz'
comboCount(250, 15, freqs = rep(2, 250))
```

## comboGeneral

**Generate Combinations and Permutations of a Vector with/without Constraints**

**Description**

- Generate combinations or permutations of a vector with or without constraints.
- Produce results in parallel using the Parallel or nThreads arguments. You can also apply each of the five compiled functions given by the argument constraintFun in parallel.
- The arguments lower and upper make it possible to generate combinations/permutations in chunks allowing for parallelization via the parallel-package. This is convenient when you want to apply a custom function to the output in parallel.
- Attack integer partition and general subset sum problems.
- GMP support allows for exploration of combinations/permutations of vectors with many elements.
- The output is in lexicographical order.

**Usage**

```r
comboGeneral(v, m = NULL, ...)  
permuteGeneral(v, m = NULL, ...)
```

```
## S3 method for class 'numeric'
comboGeneral(v, m = NULL, repetition = FALSE, freqs = NULL,
             lower = NULL, upper = NULL, constraintFun = NULL,
             comparisonFun = NULL, limitConstraints = NULL,
             keepResults = NULL, FUN = NULL, Parallel = FALSE,
             nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...)
```
## S3 method for class 'numeric'
permuteGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, constraintFun = NULL, comparisonFun = NULL, limitConstraints = NULL, keepResults = NULL, FUN = NULL, Parallel = FALSE, nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'factor'
comboGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, FUN = NULL, Parallel = FALSE, nThreads = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'factor'
permuteGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, FUN = NULL, Parallel = FALSE, nThreads = NULL, FUN.VALUE = NULL, ...)

## Default S3 method:
comboGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, FUN = NULL, FUN.VALUE = NULL, ...)

## Default S3 method:
permuteGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, FUN = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'table'
comboGeneral(v, m = NULL, lower = NULL, upper = NULL, constraintFun = NULL, comparisonFun = NULL, limitConstraints = NULL, keepResults = NULL, FUN = NULL, Parallel = FALSE, nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'table'
permuteGeneral(v, m = NULL, lower = NULL, upper = NULL, constraintFun = NULL, comparisonFun = NULL, limitConstraints = NULL, keepResults = NULL, FUN = NULL, Parallel = FALSE, nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'list'
comboGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, ...)

## S3 method for class 'list'
permuteGeneral(v, m = NULL, repetition = FALSE, freqs = NULL, lower = NULL, upper = NULL, ...)
**comboGeneral**

**Arguments**

- **v**: Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. All atomic types are supported (See is.atomic).

- **m**: Number of elements to choose. If repetition = TRUE or freqs is utilized, m can exceed the length of v. If m = NULL, the length will default to length(v) or sum(freqs).

- **...**: Further arguments passed to methods.

- **repetition**: Logical value indicating whether combinations/permutations should be with or without repetition. The default is FALSE.

- **freqs**: A vector of frequencies used for producing all combinations/permutations of a multiset of v. Each element of freqs represents how many times each element of the source vector, v, is repeated. It is analogous to the times argument in rep. The default value is NULL.

- **lower**: The lower bound. Combinations/permutations are generated lexicographically, thus utilizing this argument will determine which specific combination/permutation to start generating from (e.g. comboGeneral(5, 3, lower = 6) is equivalent to comboGeneral(5, 3)[6:choose(5, 3), ]). This argument along with upper is very useful for generating combinations/permutations in chunks allowing for easy parallelization.

- **upper**: The upper bound. Similar to lower, however this parameter allows the user to stop generation at a specific combination/permutation (e.g. comboGeneral(5, 3, upper = 5) is equivalent to comboGeneral(5, 3)[1:5, ]). If the output is constrained and lower isn’t supplied, upper serves as a cap for how many results will be returned that meet the criteria (e.g. setting upper = 100 alone will return the first 100 results that meet the criteria, while setting lower = 1 and upper = 100 will test the first 100 results against the criteria). In addition to the benefits listed for lower, this parameter is useful when the total number of combinations/permutations without constraint is large and you expect/need a small number of combinations/permutations that meet a certain criteria. Using upper can improve run time if used judiciously as we call the member function reserve of std::vector. See examples below.

- **constraintFun**: Function to be applied to the elements of v that should be passed as a string (e.g. constraintFun = "sum"). The possible constraint functions are: "sum", "prod", "mean", "max", & "min". The default is NULL, meaning no function is applied.

- **comparisonFun**: Comparison operator that will be used to compare limitConstraints with the result of constraintFun applied to v. It should be passed as a string or a vector of two strings (e.g. comparisonFun = "<=" or comparisonFun = c(">" ,"<")). The possible comparison operators are: "<", ">", "<=" ,">=" , "==". The default is NULL.

When comparisonFun is a vector of two comparison strings, e.g comparisonFun = c(comp1, comp2), and limitConstraints is a vector of two numerical values, e.g limitConstraints = c(x1, x2), the combinations/permutations will be filtered in one of the following two ways:
1. When comp1 is one of the 'greater-than' operators (i.e. ">=" or ">"), comp2 is one of the 'less-than' operators (i.e. "<=" or "<"), and \( x_1 < x_2 \), the combinations/permutations that are returned will have a value (after constraintFun has been applied) between \( x_1 \) and \( x_2 \).

2. When comp1 and comp2 are defined as in #1 and \( x_1 > x_2 \), the combinations/permutations that are returned will have a value outside the range of \( x_1 \) and \( x_2 \). See the examples below.

In other words, the first comparison operator is applied to the first limit and the second operator is applied to the second limit.

**limitConstraints**

This is the value(s) that will be used for comparison. Can be passed as a single value or a vector of two numerical values. The default is NULL. See the definition of comparisonFun as well as the examples below for more information.

**keepResults**

A logical flag indicating if the result of constraintFun applied to \( v \) should be displayed; if TRUE, an additional column of results will be added to the resulting matrix. The default is FALSE. If user is only applying constraintFun, keepResults will default to TRUE.

E.g. The following are equivalent and will produce a 4th column of row sums:

- \texttt{comboGeneral}(5, 3, constraintFun = "sum", keepResults = TRUE)
- \texttt{comboGeneral}(5, 3, constraintFun = "sum")

**FUN**

Function to be applied to each combination/permutation. The default is NULL.

**Parallel**

Logical value indicating whether combinations/permutations should be generated in parallel using \( n - 1 \) threads, where \( n \) is the maximum number of threads. The default is FALSE. If nThreads is not NULL, it will be given preference (e.g. if user has 8 threads with Parallel = TRUE and nThreads = 4, only 4 threads will be spawned). If your system is single-threaded, the arguments Parallel and nThreads are ignored.

**nThreads**

Specific number of threads to be used. The default is NULL. See Parallel.

**tolerance**

A numeric value greater than or equal to zero. This parameter is utilized when a constraint is applied on a numeric vector. The default value is 0 when it can be determined that whole values are being utilized, otherwise it is \( \sqrt{.Machine\$double.eps} \) which is approximately \( 1.5e - 8 \). N.B. If the input vector is of type integer, this parameter will be ignored and strict equality will be enforced.

**FUN.VALUE**

A template for the return value from FUN. See 'Details' of \texttt{vapply} for more information.

**Details**

For the general case, finding all combinations/permutations with constraints is optimized by organizing them in such a way that when constraintFun is applied, a partially monotonic sequence is produced. Combinations/permutations are added successively, until a particular combination exceeds the given constraint value for a given constraint/comparison function combo. After this point, we can safely skip several combinations knowing that they will exceed the given constraint value.

There are special cases where more efficient algorithms are dynamically deployed. These cases center around the subject of integer partitions. See \texttt{partitionsGeneral} for more information.
When there are any negative values in v and constraintFun = "prod", producing a monotonic set is non-trivial for the general case. As a result, performance will suffer as all combinations/permutations must be tested against the constraint criteria.

Value

- In general, a matrix with m or m + 1 columns, depending on the value of keepResults
- If FUN is utilized and FUN.VALUE = NULL, a list is returned
- When both FUN and FUN.VALUE are not NULL, the return is modeled after the return of vapply. See the ‘Value’ section of vapply.

Note

- Parallel and nThreads will be ignored in the following cases:
  - When the output is constrained (except for most partitions cases)
  - If the class of the vector passed is character, raw, and complex (N.B. Rcpp::CharacterMatrix is not thread safe). Alternatively, you can generate an indexing matrix in parallel.
  - If FUN is utilized.
- If either constraintFun, comparisonFun or limitConstraints is NULL –or– if the class of the vector passed is logical, character, raw, factor, or complex, the constraint check will not be carried out. This is equivalent to simply finding all combinations/permutations of v choose m.
- The maximum number of combinations/permutations that can be generated at one time is $2^{31} - 1$. Utilizing lower and upper makes it possible to generate additional combinations/permutations.
- Factor vectors are accepted. Class and level attributes are preserved except when FUN is used.
- Lexicographical ordering isn’t guaranteed for permutations if lower isn’t supplied and the output is constrained.
- If lower is supplied and the output is constrained, the combinations/permutations that will be tested will be in the lexicographical range lower to upper or up to the total possible number of results if upper is not given. See the second paragraph for the definition of upper.
- FUN will be ignored if the constraint check is satisfied.

Examples

comboGeneral(4, 3)
permuteGeneral(3)

permuteGeneral(factor(letters[1:3]), repetition = TRUE)

## permutations of the multiset :
## c(1,1,1,2,2,3)
permuteGeneral(table(c(1,1,1,2,2,3)))

## Example with list
comboGeneral(
  v = list(
    p1 = matrix(1:10, ncol = 2),
    p2 = data.frame(a = letters, b = 1:26),
    p3 = as.complex(1:10)
  ),
  m = 2
)

#### Examples using "upper" and "lower":
## See specific range of permutations
permuteGeneral(75, 10, freqs = rep(1:3, 25),
  lower = 1e12, upper = 1e12 + 10)

## Researcher only needs 10 7-tuples of mySamp
## such that the sum is greater than 7200.
## Generate some random data
set.seed(1009)
mySamp = rnorm(75, 997, 23)
comboGeneral(mySamp, 7, constraintFun = "sum",
  comparisonFun = ">", limitConstraints = 7200, upper = 10)

## Similarly, you can use "lower" to obtain the last rows.
## Generate the last 10 rows
comboGeneral(mySamp, 7, lower = choose(75, 7) - 9)

## Or if you would like to generate a specific chunk,
## use both "lower" and "upper". E.g. Generate one
## million combinations starting with the 900,000,001
## lexicographic combination.
t1 = comboGeneral(mySamp, 7,
  lower = 9*10^8 + 1,
  upper = 9*10^8 + 10^6)

## class of the source vector is preserved
class(comboGeneral(5,3)[1,]) == class(1:5)
class(comboGeneral(c(1,2:5),3)[1,]) == class(c(1,2:5))
class(comboGeneral(factor(month.name),3)[1,]) == class(factor(month.name))

## Using keepResults will add a column of results
comboGeneral(-3, 6, TRUE,
constraintFun = "sum",
comparisonFun = "==",
limitConstraints = -8,
keepResults = TRUE)

## Using multiple constraints:

## Get combinations such that the product
## is between 3000 and 4000 inclusive
comboGeneral(5, 7, TRUE, constraintFun = "prod",
comparisonFun = c(">=","<="),
limitConstraints = c(3000, 4000),
keepResults = TRUE)

## Or, get the combinations such that the
## product is less than or equal to 10 or
## greater than or equal to 40000
comboGeneral(5, 7, TRUE, constraintFun = "prod",
comparisonFun = c("<=",">="),
limitConstraints = c(10, 40000),
keepResults = TRUE)

#### General subset sum problem
set.seed(516781810)
comboGeneral(runif(100, 0, 42), 5, constraintFun = "mean",
comparisonFun = "==", limitConstraints = 30,
tolerance = 0.0000002)

#### Integer Partitions
comboGeneral(0:5, 5, TRUE, constraintFun = "sum",
comparisonFun = "==", limitConstraints = 5)

## Using FUN
comboGeneral(10000, 5, lower = 20, upper = 22,
FUN = function(x) {
    which(cummax(x) %% 2 == 1)
})

## Not run:
## Parallel example generating more than 2^31 - 1 combinations.
library(parallel)
numCores = detectCores() - 1

## 10086780 evenly divides choose(35, 15) and is "small enough" to
## generate quickly in chunks.
system.time(mclapply(seq(1, comboCount(35, 15), 10086780), function(x) {
    a = comboGeneral(35, 15, lower = x, upper = x + 10086779)
    ## do something
    x
}, mc.cores = numCores))
## Find 13-tuple combinations of 1:25 such
## that the mean is less than 10
system.time(myComb <- comboGeneral(25, 13, FALSE,
  constraintFun = "mean",
  comparisonFun = "<",
  limitConstraints = 10))

## Alternatively, you must generate all combinations and subsequently
## subset to obtain the combinations that meet the criteria
system.time(myComb2 <- combn(25, 13))
system.time(myCols <- which(colMeans(myComb2) < 10))
system.time(myComb2 <- myComb2[, myCols])

## Any variation is much slower
system.time(myComb2 <- combn(25, 13)[, combn(25, 13, mean) < 10])

## Test equality with myComb above
all.equal(myComb, t(myComb2))

## Fun example... see stackoverflow:
## https://stackoverflow.com/q/22218640/4408538
system.time(permuteGeneral(seq(0L, 100L, 10L), 8, TRUE,
  constraintFun = "sum",
  comparisonFun = "==",
  limitConstraints = 100))

## These are called weak integer compositions. Below, we call
## compositionsGeneral which gives the same output except it
## in lexicographical order. See 'Note' above
system.time(compositionsGeneral(seq(0L, 100L, 10L), 8, TRUE, weak = TRUE))

## End(Not run)

### comboGrid

#### Efficient Version of expand.grid Where order Does Not Matter

**Description**

This function efficiently generates Cartesian-product-like output where order does not matter. It is loosely equivalent to the following:

- `t = expand.grid(list)`
- `t = t[do.call(order, t), ]`
- `key = apply(t, 1, function(x) paste0(sort(x), collapse = ""))`
- `t[!duplicated(key), ]`

**Usage**

comboGrid(..., repetition = TRUE)
comboGroups

Partition a Vector into Groups

Description

- Generate partitions of a vector into groups. See Create Combinations in R by Groups on https://stackoverflow.com for a direct use case of when the groups sizes are equal.
- Produce results in parallel using the Parallel or nThreads arguments.
- GMP support allows for exploration where the number of results is large.
- The output is in lexicographical order by groups.

Usage

comboGroups(v, numGroups = NULL, grpSizes = NULL,
            retType = "matrix", lower = NULL, upper = NULL,
            Parallel = FALSE, nThreads = NULL)
comboGroups

Arguments

\(v\)  
Source vector. If \(v\) is a positive integer, it will be converted to the sequence \(1:v\). If \(v\) is a negative integer, it will be converted to the sequence \(v:-1\). All atomic types are supported (See \texttt{is.atomic}).

\texttt{numGroups}\  
An Integer. The number of groups that the vector will be partitioned into. The default is \texttt{NULL}. If provided and \texttt{grpSize} is \texttt{NULL}, it must divide the length of \(v\) (if \(v\) is a vector) or \(v\) (if \(v\) is a scalar).

\texttt{grpSizes}\  
A vector of whole numbers representing the size of each group. The default is \texttt{NULL}. If provided, the sum of the elements must total the length of \(v\) (if \(v\) is a vector) or \(v\) (if \(v\) is a scalar).

\texttt{retType}\  
A string, "3Darray" or "matrix", that determines the shape of the output. The default is "matrix". Note, "3Darray" can only be used when the size of each group is uniform. When the size of each group varies, the return output will always be a matrix.

\texttt{lower}\  
The lower bound. Partitions of groups are generated lexicographically, thus utilizing this argument will determine which specific result to start generating from (e.g. \texttt{comboGroups(8, 2, lower = 30)} is equivalent to \texttt{comboGroups(8, 2)[30:comboGroupsCount(8, 2), ]}). This argument along with \texttt{upper} is very useful for generating results in chunks allowing for easy parallelization.

\texttt{upper}\  
The upper bound. Similar to \texttt{lower}, however this parameter allows the user to stop generation at a specific result (e.g. \texttt{comboGroups(8, 2, upper = 5)} is equivalent to \texttt{comboGroups(8, 2)[1:5, ]})

\texttt{Parallel}\  
Logical value indicating whether results should be generated in parallel using \(n - 1\) threads, where \(n\) is the maximum number of threads. The default is \texttt{FALSE}. If \texttt{nThreads} is not \texttt{NULL}, it will be given preference (e.g. if user has 8 threads with \texttt{Parallel = TRUE} and \texttt{nThreads = 4}, only 4 threads will be spawned). If your system is single-threaded, the arguments \texttt{Parallel} and \texttt{nThreads} are ignored.

\texttt{nThreads}\  
Specific number of threads to be used. The default is \texttt{NULL}. See \texttt{Parallel}.

Details

Conceptually, this problem can be viewed as generating all permutations of the vector \(v\) and removing the within group permutations. To illustrate this, let us consider the case of generating partitions of \(1:8\) into 2 groups each of size 4.

- To begin, generate the permutations of \(1:8\) and group the first/last four elements of each row.

```
<table>
<thead>
<tr>
<th>C1</th>
<th>C2</th>
<th>C3</th>
<th>C4</th>
<th>C5</th>
<th>C6</th>
<th>C7</th>
<th>C8</th>
</tr>
</thead>
<tbody>
<tr>
<td>R1</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>6</td>
<td>7</td>
</tr>
<tr>
<td>R2</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>6</td>
<td>8</td>
</tr>
<tr>
<td>R3</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>7</td>
<td>6</td>
</tr>
<tr>
<td>R4</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>7</td>
<td>8</td>
</tr>
<tr>
<td>R5</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>8</td>
<td>6</td>
</tr>
<tr>
<td>R6</td>
<td>11</td>
<td>2</td>
<td>3</td>
<td>41</td>
<td>15</td>
<td>8</td>
<td>7</td>
</tr>
</tbody>
</table>
```
• Note that the permutations above are equivalent partitions of 2 groups of size 4 as only the last four elements are permuted. If we look at at the 25th lexicographical permutation, we observe our second distinct partition.

<table>
<thead>
<tr>
<th></th>
<th>Grp1</th>
<th>Grp2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>C1</td>
<td>C2</td>
</tr>
<tr>
<td>R24</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>R25</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>R26</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>R27</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>R28</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

• Continuing on, we will reach the 3,457th lexicographical permutation, which represents the last result:

<table>
<thead>
<tr>
<th></th>
<th>Grp1</th>
<th>Grp2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>C1</td>
<td>C2</td>
</tr>
<tr>
<td>R3454</td>
<td>11</td>
<td>6</td>
</tr>
<tr>
<td>R3455</td>
<td>11</td>
<td>6</td>
</tr>
<tr>
<td>R3456</td>
<td>11</td>
<td>6</td>
</tr>
<tr>
<td><strong>R3457</strong></td>
<td>11</td>
<td>6</td>
</tr>
<tr>
<td>R3458</td>
<td>11</td>
<td>6</td>
</tr>
</tbody>
</table>

• For this small example, the method above will not be that computationally expensive. In fact, there are only 35 total partitions of 1:8 into 2 groups of size 4 out of a possible \( \text{factorial}(8) = 40320 \) permutations. However, just doubling the size of the vector will make this approach infeasible as there are over 10 trillion permutations of 1:16.

• The algorithm in comboGroups avoids these duplicate partitions of groups by utilizing an efficient algorithm analogous to the `std::next_permutation` found in the standard algorithm library in C++.

**Value**

By default, a matrix is returned with column names corresponding to the associated group. If `retType = "3Darray"`, a named 3D array is returned.

**Note**

• The maximum number of partitions of groups that can be generated at one time is \( 2^{31} - 1 \). Utilizing `lower` and `upper` makes it possible to generate additional combinations/permutations.

• The length of `grpSizes` must equal `numGroups` if both `grpSize` and `numGroups` are provided.

**Author(s)**

Joseph Wood
Examples

```
## return a matrix
comboGroups(8, 2)

## or a 3 dimensional array
temp = comboGroups(8, 2, retType = "3Darray")

## view the first partition
temp[1, , ]

## Example with groups of varying size
comboGroups(8, grpSizes = c(3, 5))

total = comboGroupsCount(11, grpSizes = c(3, 3, 5))

## Start generating from particular index
comboGroups(11, grpSizes = c(3, 3, 5), lower = total - 20)
```

---

**Description**

The `ComboGroups` class is an S4-class that exposes C++ classes that provide access to iterators and other useful methods.

**Slots**

- `nextIter` Retrieve the **next** lexicographical result
- `nextNIter` Pass an integer `n` to retrieve the **next n** lexicographical results
- `nextRemaining` Retrieve all remaining lexicographical results
- `currIter` Returns the current iteration
- `startOver` Resets the iterator
- `sourceVector` View the source vector
- `summary` Returns a list of summary information about the iterator
- `front` Retrieve the **first** lexicographical result
- `back` Retrieve the **last** lexicographical result
- `randomAccess` Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.

Combo-class, Constraints-class, Partitions-class

Examples

showClass("ComboGroups")

table(comboGroupsCount, name = "Number of Partitions of a Vector into Groups")

Description

Calculate the number of partitions of a vector into groups. See the related integer sequences A025035-A025042 at OEIS (E.g. A025036 for Number of partitions of $1, 2, ..., 4n$ into sets of size 4.)

Usage

comboGroupsCount(v, numGroups = NULL, grpSizes = NULL)

Arguments

v Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. All atomic types are supported (See is.atomic).

numGroups An Integer. The number of groups that the vector will be partitioned into. The default is NULL. If provided and grpSize is NULL, it must divide the length of v (if v is a vector) or v (if v is a scalar).

grpSizes A vector of whole numbers representing the size of each group. The default is NULL. If provided, the sum of the elements must total the length of v (if v is a vector) or v (if v is a scalar).

Value

A numerical value representing the total number of partitions of groups.

Note

When the number of results exceeds $2^{53} - 1$, a number of class bigz is returned.

Author(s)

Joseph Wood

References

OEIS Integer Sequence A025036
Examples

    comboGroupsCount(16, 4)
    comboGroupsCount(16, grpSizes = c(1:4, 6))
    comboGroupsCount(28, grpSizes = rep(2:5, each = 2))

Description

- Returns an iterator for iterating over partitions of a vector into groups.
- Supports random access via the [[ method.
- GMP support allows for exploration of cases where the number of comboGroups is large.
- Use the next methods to obtain results in lexicographical order.

Usage

    comboGroupsIter(v, numGroups = NULL, grpSizes = NULL,
                    retType = "matrix", Parallel = FALSE,
                    nThreads = NULL)

Arguments

- **v**
  - Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. All atomic types are supported (See is.atomic).
- **numGroups**
  - An Integer. The number of groups that the vector will be partitioned into. The default is NULL. If provided and grpSize is NULL, it must divide the length of v (if v is a vector) or v (if v is a scalar).
- **grpSizes**
  - A vector of whole numbers representing the size of each group. The default is NULL. If provided, the sum of the elements must total the length of v (if v is a vector) or v (if v is a scalar).
- **retType**
  - A string, "3Darray" or "matrix", that determines the shape of the output. The default is "matrix". Note, "3Darray" can only be used when the size of each group is uniform. When the size of each group varies, the return output will always be a matrix.
- **Parallel**
  - Logical value indicating whether results should be generated in parallel using n−1 threads, where n is the maximum number of threads. The default is FALSE. If nThreads is not NULL, it will be given preference (e.g. if user has 8 threads with Parallel = TRUE and nThreads = 4, only 4 threads will be spawned). If your system is single-threaded, the arguments Parallel and nThreads are ignored.
- **nThreads**
  - Specific number of threads to be used. The default is NULL. See Parallel.
Details

Once you initialize a new iterator, the following methods are available:

- `nextIter` Retrieve the next lexicographical result
- `nextNIter` Pass an integer $n$ to retrieve the next $n$ lexicographical results
- `nextRemaining` Retrieve all remaining lexicographical results
- `currIter` Returns the current iteration
- `startOver` Resets the iterator
- `sourceVector` View the source vector
- `summary` Returns a list of summary information about the iterator
- `front` Retrieve the first lexicographical result
- `back` Retrieve the last lexicographical result

Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.

Value

- If `nextIter` is called, a named vector is returned if `retType = "matrix"`. If `retType = "3Darray"`, a named matrix is returned.
- Otherwise a named matrix is returned when `retType = "matrix"` and a named 3D array is returned when `retType = "3Darray"`.

Note

- If `nThreads` is utilized, it will only take effect if the number of elements requested is greater than some threshold (determined internally). E.g:

  ```r
  serial <- comboGroupsIter(50, 10)
  multi <- comboGroupsIter(50, 10, nThreads = 4)
  fetch1e6 <- multi@nextNIter(1e6)  # much faster than serial@nextNIter(1e6)
  fetch1e3 <- multi@nextNIter(1e3)  # only one thread used... same as serial@nextNIter(1e3)
  ```

  ```r
  library(microbenchmark)
  microbenchmark(multi@nextNIter(1e6), serial@nextNIter(1e6), times = 20)
  microbenchmark(multi@nextNIter(1e3), serial@nextNIter(1e3), times = 20)
  ```

- The maximum number of comboGroups that can be generated at one time is $2^{31} - 1$.

a@summary()
a@back()
a[[5]]
a@summary()
a[[c(1, 17, 3)]]
a@summary()
```

### comboGroupsSample

**Sample Partitions of a Vector into Groups**

**Description**
- Generate a specific (lexicographically) or random sample of partitions of groups.
- Produce results in parallel using the `Parallel` or `nThreads` arguments.
- GMP support allows for exploration where the number of results is large.

**Usage**

```r
comboGroupsSample(v, numGroups = NULL, grpSizes = NULL, retType = "matrix",
                  n = NULL, sampleVec = NULL, seed = NULL, Parallel = FALSE,
                  nThreads = NULL, namedSample = FALSE)
```

**Arguments**

- **v**: Source vector. If `v` is a positive integer, it will be converted to the sequence `1:v`. If `v` is a negative integer, it will be converted to the sequence `v:-1`. All atomic types are supported (See `is.atomic`).
- **numGroups**: An Integer. The number of groups that the vector will be partitioned into. The default is `NULL`. If provided and `grpSizes` is `NULL`, it must divide the length of `v` (if `v` is a vector) or `v` (if `v` is a scalar).
- **grpSizes**: A vector of whole numbers representing the size of each group. The default is `NULL`. If provided, the sum of the elements must total the length of `v` (if `v` is a vector) or `v` (if `v` is a scalar).
- **retType**: A string, "3Darray" or "matrix", that determines the shape of the output. The default is "matrix". Note, "3Darray" can only be used when the size of each group is uniform. When the size of each group varies, the return output will always be a matrix.
- **n**: Number of results to return. The default is `NULL`. 
<table>
<thead>
<tr>
<th>Parameter</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>sampleVec</td>
<td>A vector of numbers representing the lexicographical partition of groups to return. Accepts vectors of class bigz as well as vectors of characters</td>
</tr>
<tr>
<td>seed</td>
<td>Random seed initialization. The default is NULL. N.B. If the gmp library is needed, this parameter must be set in order to have reproducible results (E.g set.seed() has no effect in these cases).</td>
</tr>
<tr>
<td>Parallel</td>
<td>Logical value indicating whether results should be generated in parallel. The default is FALSE. If TRUE and nThreads = NULL, the number of threads used is equal to the minimum of one minus the number of threads available on your system and the number of results requested (e.g. if user has 16 threads and only needs 5 results, 5 threads will be used (i.e. ( \min(16 - 1, 5) = 5 )). If nThreads is not NULL, it will be given preference (e.g. if user has 8 threads with Parallel = TRUE and nThreads = 4, only 4 threads will be spawned). If your system is single-threaded, the arguments Parallel and nThreads are ignored.</td>
</tr>
<tr>
<td>nThreads</td>
<td>Specific number of threads to be used. The default is NULL. See Parallel.</td>
</tr>
<tr>
<td>namedSample</td>
<td>Logical flag. If TRUE, rownames corresponding to the lexicographical result, will be added to the returned matrix. The default is FALSE.</td>
</tr>
</tbody>
</table>

**Details**

These algorithms rely on efficiently generating the \( n^{th} \) lexicographical result.

**Value**

By default, a matrix is returned with column names corresponding to the associated group. If retType = "3Darray", a 3D array is returned.

Lexicographical order

**Examples**

```r
## generate 10 random partitions of groups of equal size
comboGroupsSample(10, 2, n = 10, seed = 123)

## generate 10 random partitions of groups of varying sizes
comboGroupsSample(10, grpSizes = 1:4, n = 10, seed = 123)

## using sampleVec to generate specific results
comboGroupsSample(15, 5, sampleVec = c(1, 100, 1e3, 1e6))

all.equal(comboGroupsSample(10, 5,
    sampleVec = 1:comboGroupsCount(10, 5)),
    comboGroups(10, 5))

## Examples with enormous number of total results
```
num = comboGroupsCount(100, 20)
gmp::log2.bigz(num)
## [1] 325.5498

first = gmp::urand.bigz(n = 1, size = 325, seed = 123)
mySamp = do.call(c, lapply(0:10, function(x) gmp::add.bigz(first, x)))

class(mySamp)
## [1] "bigz"

## using the sampling function
cbgSamp = comboGroupsSample(100, 20, sampleVec = mySamp)

## using the standard function
cbgGeneral = comboGroups(100, 20,
                        lower = first,
                        upper = gmp::add.bigz(first, 10))

identical(cbgSamp, cbgGeneral)
## [1] TRUE

## Not run:
## Using Parallel
system.time(comboGroupsSample(1000, 20, n = 80, seed = 10, Parallel = TRUE))

## End(Not run)

comboIter  

**Combination and Permutation Iterator**

**Description**

- Returns an iterator for iterating over combinations or permutations of a vector with or without constraints.
- Supports random access via the \[\] method.
- GMP support allows for exploration of combinations/permutations of vectors with many elements.
- The output is in lexicographical order for the next methods and reverse lexicographical order for the prev methods.
- Learn more in vignette("iterators").

**Usage**

```r
comboIter(v, m = NULL, ...)
permuteIter(v, m = NULL, ...)
```

## S3 method for class 'numeric'
comboIter(v, m = NULL, repetition = FALSE, freqs = NULL,
constraintFun = NULL, comparisonFun = NULL,
limitConstraints = NULL, keepResults = NULL,
FUN = NULL, Parallel = FALSE, nThreads = NULL,
tolerance = NULL, FUN.VALUE = NULL, ...)

## S3 method for class 'numeric'

  Parallel = FALSE, nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...
)

## S3 method for class 'table'
permuteIter(
  v, m = NULL, constraintFun = NULL, comparisonFun = NULL,
  limitConstraints = NULL, keepResults = NULL, FUN = NULL,
  Parallel = FALSE, nThreads = NULL, tolerance = NULL, FUN.VALUE = NULL, ...
)

## S3 method for class 'list'
comboIter

comboIter(v, m = NULL, repetition = FALSE, freqs = NULL, ...)

## S3 method for class 'list'
permuteIter(v, m = NULL, repetition = FALSE, freqs = NULL, ...)

Arguments

v  Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. All atomic types are supported (See is.atomic).

m  Number of elements to choose. If repetition = TRUE or freqs is utilized, m can exceed the length of v. If m = NULL, the length will default to \text{length}(v) or \text{sum}(freqs).

... Further arguments passed to methods.

repetition Logical value indicating whether combinations/permutations should be with or without repetition. The default is FALSE.

freqs A vector of frequencies used for producing all combinations/permutations of a multiset of v. Each element of freqs represents how many times each element of the source vector, v, is repeated. It is analogous to the times argument in \text{rep}. The default value is NULL.

constraintFun Function to be applied to the elements of v that should be passed as a string (e.g. constraintFun = "sum"). The possible constraint functions are: "sum", "prod", "mean", "max", & "min". The default is NULL, meaning no function is applied.

comparisonFun Comparison operator that will be used to compare limitConstraints with the result of constraintFun applied to v. It should be passed as a string or a vector of two strings (e.g. comparisonFun = "<=" or comparisonFun = c(">","<")). The possible comparison operators are: ",",">", "<=" or "<=". The default is NULL.

When comparisonFun is a vector of two comparison strings, e.g. comparisonFun = c(comp1, comp2), and limitConstraints is a vector of two numerical values, e.g. limitConstraints = c(x1, x2), the combinations/permutations will be filtered in one of the following two ways:

1. When comp1 is one of the 'greater-than' operators (i.e. ",=" or ",>") and comp2 is one of the 'less-than' operators (i.e. ",=" or ","), and x1 < x2, the combinations/permutations that are returned will have a value (after constraintFun has been applied) between x1 and x2.

2. When comp1 and comp2 are defined as in #1 and x1 > x2, the combinations/permutations that are returned will have a value outside the range of x1 and x2. See the examples below.

In other words, the first comparison operator is applied to the first limit and the second operator is applied to the second limit.

limitConstraints

This is the value(s) that will be used for comparison. Can be passed as a single value or a vector of two numerical values. The default is NULL. See the definition of comparisonFun as well as the examples below for more information.
keepResults A logical flag indicating if the result of constraintFun applied to v should be displayed; if TRUE, an additional column of results will be added to the resulting matrix. The default is FALSE. If user is only applying constraintFun, keepResults will default to TRUE.

FUN Function to be applied to each combination/permutation. The default is NULL.

Parallel Logical value indicating whether combinations/permutations should be generated in parallel using \( n - 1 \) threads, where \( n \) is the maximum number of threads. The default is FALSE. If nThreads is not NULL, it will be given preference (e.g. if user has 8 threads with Parallel = TRUE and nThreads = 4, only 4 threads will be spawned). If your system is single-threaded, the arguments Parallel and nThreads are ignored.

nThreads Specific number of threads to be used. The default is NULL. See Parallel.

tolerance A numeric value greater than or equal to zero. This parameter is utilized when a constraint is applied on a numeric vector. The default value is 0 when it can be determined that whole values are being utilized, otherwise it is \( \sqrt{\text{.Machine}$\text{double}\$\text{eps}} \) which is approximately \( 1.5e - 8 \). N.B. If the input vector is of type integer, this parameter will be ignored and strict equality will be enforced.

FUN.VALUE A template for the return value from FUN. See ‘Details’ of vapply for more information.

Details

Once you initialize a new iterator, the following methods are available via @ (e.g. a@nextIter()) or $(e.g. a$nextIter()). The preferred practice is to use @ as it is much more efficient (See examples below). Also note that not all of the methods below are available in all cases. See Combo-class, Constraints-class, and Partitions-class:

nextIter Retrieve the next lexicographical result
nextNIter Pass an integer \( n \) to retrieve the next \( n \) lexicographical results
nextRemaining Retrieve all remaining lexicographical results
currIter Returns the current iteration
prevIter Retrieve the previous lexicographical result (the next reverse lexicographical result)
prevNIter Pass an integer \( n \) to retrieve the previous \( n \) lexicographical results (the next \( n \) reverse lexicographical results)
prevRemaining Retrieve all remaining reverse lexicographical results
startOver Resets the iterator
sourceVector View the source vector
summary Returns a list of summary information about the iterator
front Retrieve the first lexicographical result
back Retrieve the last lexicographical result

[[ Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.
comboIter

Value

- If `nextIter` or `prevIter` is called, a vector is returned
- Otherwise, a matrix with \( m \) or \( m + 1 \) columns, depending on the value of `keepResults`
- If `FUN` is utilized, `FUN.VALUE = NULL`, and either `nextIter` or `prevIter` is called, the result will be determined by `FUN`, otherwise a list is returned.
- When both `FUN` and `FUN.VALUE` are not `NULL`, the return is modeled after the return of `vapply`. See the ‘Value’ section of `vapply`.

Note

- Parallel and nThreads will be ignored in the following cases:
  - When the output is constrained (except for most partitions cases)
  - If the class of the vector passed is `character`, `raw`, and `complex` (N.B. `Rcpp::CharacterMatrix` is not thread safe). Alternatively, you can generate an indexing matrix in parallel.
  - If `FUN` is utilized.
- If either `constraintFunc`, `comparisonFunc` or `limitConstraints` is `NULL` –or– if the class of the vector passed is `logical`, `character`, `raw`, `factor`, or `complex`, the constraint check will not be carried out. This is equivalent to simply finding all combinations/permutations of \( v \) choose \( m \).
- The maximum number of combinations/permutations that can be generated at one time is \( 2^{31} - 1 \).
- Factor vectors are accepted. Class and level attributes are preserved except when `FUN` is used.
- Lexicographical ordering isn’t guaranteed for permutations if the output is constrained.
- `FUN` will be ignored if the constraint check is satisfied.

a@front()
a@nextRemaining()
```
comboRank

Rank Combinations and Permutations

Description

- Generate the rank (lexicographically) of combinations/permutations. These functions are the complement to comboSample and permuteSample. See the examples below.
- GMP support allows for exploration of combinations/permutations of vectors with many elements.

Usage

comboRank(..., v, repetition = FALSE, freqs = NULL)
permuteRank(..., v, repetition = FALSE, freqs = NULL)
comboRank

Arguments

... vectors or matrices to be ranked.

v Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. All atomic types are supported (See is.atomic).

repetition Logical value indicating whether combinations/permutations should be with or without repetition. The default is FALSE.

freqs A vector of frequencies used for producing all combinations/permutations of a multiset of v. Each element of freqs represents how many times each element of the source vector, v, is repeated. It is analogous to the times argument in rep. The default value is NULL.

Details

These algorithms rely on efficiently ranking the \(n^{th}\) lexicographical combination/permutation.

Value

A vector of class integer, numeric, or bigz determined by the total number of combinations/permutations

Note

v must be supplied.

comboSample(
  v, m = NULL, repetition = FALSE, freqs = NULL, n = NULL,
  sampleVec = NULL, seed = NULL, namedSample = FALSE, ...
)
```

```r
## S3 method for class 'list'
permuteSample(
  v, m = NULL, repetition = FALSE, freqs = NULL, n = NULL,
  sampleVec = NULL, seed = NULL, namedSample = FALSE, ...
)
```

### Arguments

- `v` Source vector. If `v` is a positive integer, it will be converted to the sequence `1:v`. If `v` is a negative integer, it will be converted to the sequence `v:-1`. All atomic types are supported (See `is.atomic`).
- `m` Number of elements to choose. If `repetition` = TRUE or `freqs` is utilized, `m` can exceed the length of `v`. If `m = NULL`, the length will default to `length(v)` or `sum(freqs)`.  
- `...` Further arguments passed to methods.
- `repetition` Logical value indicating whether combinations/permutations should be with or without repetition. The default is FALSE.
- `freqs` A vector of frequencies used for producing all combinations/permutations of a multiset of `v`. Each element of `freqs` represents how many times each element of the source vector, `v`, is repeated. It is analogous to the `times` argument in `rep`. The default value is NULL.
- `n` Number of combinations/permutations to return. The default is NULL.
- `sampleVec` A vector of indices representing the lexicographical combination/permutations to return. Accepts whole numbers as well as vectors of class `bigz` as well as vectors of characters
- `seed` Random seed initialization. The default is NULL. N.B. If the gmp library is needed, this parameter must be set in order to have reproducible results (E.g `set.seed()` has no effect in these cases).
**FUN** Function to be applied to each combination/permutation. The default is NULL.

**Parallel** Logical value indicating whether combinations/permutations should be generated in parallel. The default is FALSE. If TRUE and nThreads = NULL, the number of threads used is equal to the minimum of one minus the number of threads available on your system and the number of results requested (e.g. if user has 16 threads and only needs 5 results, 5 threads will be used (i.e. \( \min(16 - 1, 5) = 5 \)). If nThreads is not NULL, it will be given preference (e.g. if user has 8 threads with Parallel = TRUE and nThreads = 4, only 4 threads will be spawned). If your system is single-threaded, the arguments Parallel and nThreads are ignored.

**nThreads** Specific number of threads to be used. The default is NULL. See Parallel.

**namedSample** Logical flag. If TRUE, rownames corresponding to the lexicographical combination/permutation, will be added to the returned matrix. The default is FALSE.

**FUN.VALUE** A template for the return value from FUN. See 'Details' of `vapply` for more information.

### Details
These algorithms rely on efficiently generating the \( n^{th} \) lexicographical combination/permutation. This is the process of **unranking**.

### Value
- In general, a matrix with \( m \) or \( m + 1 \) columns, depending on the value of keepResults
- If FUN is utilized and FUN.VALUE = NULL, a list is returned
- When both FUN and FUN.VALUE are not NULL, the return is modeled after the return of `vapply`. See the 'Value' section of `vapply`.

### Note
- Parallel and nThreads will be ignored in the following cases:
  - If the class of the vector passed is character (N.B. Rcpp::CharacterMatrix is not thread safe). Alternatively, you can generate an indexing matrix in parallel.
  - If FUN is utilized.
- \( n \) and sampleVec cannot both be NULL.
- Factor vectors are accepted. Class and level attributes are preserved except when FUN is used.

```r
## generate 10 random combinations
comboSample(30, 8, TRUE, n = 5, seed = 10)

## Using sampleVec to generate specific permutations
fqs = c(1,2,2,1,2,1,2,2,1,2,1,2,1,2,1,1)
s_idx = c(1, 10^2, 10^5, 10^8, 10^11)
permuteSample(15, 10, freqs = fqs, sampleVec = s_idx)

## Same example using 'table' method
permuteSample(table(rep(1:15, times = fqs)), 10, sampleVec = s_idx)

## Generate each result one by one...
## Same, but not as efficient as generating iteratively
all.equal(comboSample(10, 5, sampleVec = 1:comboCount(10, 5)),
          comboGeneral(10, 5))

## Examples with enormous number of total permutations
num = permuteCount(10000, 20)
gmp::log2.bigz(num)
first = gmp::urand.bigz(n = 1, size = 265, seed = 123)
mySamp = do.call(c, lapply(0:10, function(x) gmp::add.bigz(first, x)))
class(mySamp)

## using permuteSample
pSamp = permuteSample(10000, 20, sampleVec = mySamp)

## using permuteGeneral
pGeneral = permuteGeneral(10000, 20,
                          lower = first,
                          upper = gmp::add.bigz(first, 10))

identical(pSamp, pGeneral)

## Using nThreads
permPar = permuteSample(10000, 50, n = 8, seed = 10, nThreads = 2)

## Using FUN
permuteSample(10000, 50, n = 4, seed = 10, FUN = sd)

## Not run:
## Using Parallel
permuteSample(10000, 50, n = 80, seed = 10, Parallel = TRUE)

## End(Not run)
```
Description

The Constraints class is an S4-class that exposes C++ classes that provide access to iterators and other useful methods.

Slots

- `nextIter` Retrieve the next lexicographical result
- `nextNIter` Pass an integer \( n \) to retrieve the next \( n \) lexicographical results
- `nextRemaining` Retrieve all remaining lexicographical results
- `currIter` Returns the current iteration
- `startOver` Resets the iterator
- `sourceVector` View the source vector
- `summary` Returns a list of summary information about the iterator

### divisorsRcpp

**Vectorized Factorization (Complete)**

**Description**

Function for generating the complete factorization for a vector of numbers.

**Usage**

```r
divisorsRcpp(v, namedList = FALSE, nThreads = NULL)
```

**Arguments**

- **v** Vector of integers or numeric values. Non-integral values will be coerced to whole numbers.
- **namedList** Logical flag. If TRUE and the length(v) > 1, a named list is returned. The default is FALSE.
- **nThreads** Specific number of threads to be used. The default is NULL.
divisorsRcpp

Details
Efficient algorithm that builds on primeFactorize to generate the complete factorization of many numbers.

Value
- Returns an unnamed vector if length(v) == 1 regardless of the value of namedList. If v < $2^{31}$, the class of the returned vector will be integer, otherwise the class will be numeric.
- If length(v) > 1, a named/unnamed list of vectors will be returned. If max(bound1, bound2) < $2^{31}$, the class of each vector will be integer, otherwise the class will be numeric.

Note
The maximum value for each element in v is $2^{53} - 1$.

## Get the complete factorization of a single number
divisorsRcpp(10^8)

## Or get the complete factorization of many numbers
set.seed(29)
myVec <- sample(-1000000:1000000, 1000)
system.time(myFacs <- divisorsRcpp(myVec))

## Return named list
myFacsWithNames <- divisorsRcpp(myVec, namedList = TRUE)

## Using nThreads
system.time(divisorsRcpp(myVec, nThreads = 2))
```
divisorsSieve  

Generate Complete Factorization for Numbers in a Range

Description

Sieve that generates the complete factorization of all numbers between bound1 and bound2 (if supplied) or all numbers up to bound1.

Usage

divisorsSieve(bound1, bound2 = NULL, namedList = FALSE, nThreads = NULL)

Arguments

bound1  Positive integer or numeric value.
bound2  Positive integer or numeric value.
namedList  Logical flag. If TRUE, a named list is returned. The default is FALSE.
nThreads  Specific number of threads to be used. The default is NULL.

Details

This function is useful when many complete factorizations are needed. Instead of generating the complete factorization on the fly, one can reference the indices/names of the generated list.

This algorithm benefits greatly from the fast integer division library ‘libdivide’. The following is from https://libdivide.com/:

- “libdivide allows you to replace expensive integer divides with comparatively cheap multiplication and bitshifts. Compilers usually do this, but only when the divisor is known at compile time. libdivide allows you to take advantage of it at runtime. The result is that integer division can become faster - a lot faster.”

Value

Returns a named/unnamed list of integer vectors if max(bound1, bound2) < 2^{31}, or a list of numeric vectors otherwise.

Note

The maximum value for either of the bounds is 2^{53} − 1.

mySamp <- sample(10^5, 5*10^4)

## Generate complete factorizations up
## to 10^5 (max element from mySamp)
system.time(allFacs <- divisorsSieve(10^5))

## Use generated complete factorization for further
## analysis by accessing the index of allFacs
for (s in mySamp) {
  myFac <- allFacs[[s]]
  ## Continue algorithm
}

## Generating complete factorizations over
## a range is efficient as well
system.time(divisorsSieve(10^12, 10^12 + 10^5))

## Use nThreads for improved efficiency
system.time(divisorsSieve(10^12, 10^12 + 10^5, nThreads = 2))

## Set 'namedList' to TRUE to return a named list
divisorsSieve(27, 30, namedList = TRUE)

## Using nThreads
system.time(divisorsSieve(1e5, 2e5, nThreads = 2))
```

eulerPhiSieve

Apply Euler’s Phi Function to Every Element in a Range

Description

Sieve that generates the number of coprime elements for every number between bound1 and bound2 (if supplied) or all numbers up to bound1. This is equivalent to applying Euler’s phi function (often written as \(\phi(x)\)) to every number in a given range.
Usage

eulerPhiSieve(bound1, bound2 = NULL, namedVector = FALSE, nThreads = NULL)

Arguments

bound1 Positive integer or numeric value.
bound2 Positive integer or numeric value.
namedVector Logical flag. If TRUE, a named vector is returned. The default is FALSE.
nThreads Specific number of threads to be used. The default is NULL.

Details

For the simple case (i.e. when bound2 = NULL), this algorithm first generates all primes up to \(n\) via the sieve of Eratosthenes. We use these primes to sieve over the sequence \(1:n\), dividing each value by \(p\), creating a temporary value that will be subtracted from the original value at each index (i.e. equivalent to multiply each index by \((1 - 1/p)\) but more efficient as we don’t have to deal with floating point numbers). The case when is.null(bound2) = FALSE is more complicated but the basic ideas still hold.

This function is very useful when you need to calculate Euler’s phi function for many numbers in a range as performing this calculation on the fly can be computationally expensive.

This algorithm benefits greatly from the fast integer division library ‘libdivide’. The following is from https://libdivide.com/:

• “‘libdivide allows you to replace expensive integer divides with comparatively cheap multiplication and bitshifts. Compilers usually do this, but only when the divisor is known at compile time. libdivide allows you to take advantage of it at runtime. The result is that integer division can become faster - a lot faster.’”

Value

Returns a named/unnamed integer vector if \(\max(bound1, bound2) < 2^{31}\), or a numeric vector otherwise.

Note

The maximum allowed value is \(2^{53} - 1\).

### isPrimeRcpp

**Vectorized Primality Test**

**Description**

Implementation of the Miller-Rabin primality test. Based on the "mp_prime_p" function from the "factorize.c" source file found in the gmp library: [https://gmplib.org](https://gmplib.org).

**Usage**

```r
isPrimeRcpp(v, namedVector = FALSE, nThreads = NULL)
```

**Arguments**

- `v` Vector of integers or numeric values.
- `namedVector` Logical flag. If `TRUE`, a named vector is returned. The default is `FALSE`.
- `nThreads` Specific number of threads to be used. The default is `NULL`.  

Details

The Miller-Rabin primality test is a probabilistic algorithm that makes heavy use of modular exponentiation. At the heart of modular exponentiation is the ability to accurately obtain the remainder of the product of two numbers \((\text{mod } p)\).

With the gmp library, producing accurate calculations for problems like this is trivial because of the nature of the multiple precision data type. However, standard C++ does not afford this luxury and simply relying on a strict translation would have limited this algorithm to numbers less than \(\sqrt{2^{53}} - 1\) (N.B. We are taking advantage of the signed 64-bit fixed width integer from the stdint library in C++). If we were confined to base R, the limit would have been \(\sqrt{2^{53}} - 1\). RcppAlgos::isPrimeRcpp gets around this limitation with a divide and conquer approach taking advantage of properties of arithmetic.

The problem we are trying to solve can be summarized as follows:

\[(x_1 \ast x_2) \pmod{p}\]

Now, we rewrite \(x_2\) as \(x_2 = y_1 + y_2 + \cdots + y_n\), so that we obtain:

\[(x_1 \ast y_1) \pmod{p} + (x_1 \ast y_2) \pmod{p} + \cdots + (x_1 \ast y_n) \pmod{p}\]

Where each product \((x_1 \ast y_j)\) for \(j \leq n\) is smaller than the original \(x_1 \ast x_2\). With this approach, we are now capable of handling much larger numbers. Many details have been omitted for clarity.

For a more in depth examination of this topic see Accurate Modular Arithmetic with Double Precision.

Value

Returns a named/unnamed logical vector. If an index is TRUE, the number at that index is prime, otherwise the number is composite.

Note

The maximum value for each element in \(v\) is \(2^{53} - 1\).

**numDivisorSieve**

*Apply Divisor Function to Every Element in a Range*

**Description**

Sieve that generates the number of divisors for every number between `bound1` and `bound2` (if supplied) or all numbers up to `bound1`. This is equivalent to applying the divisor function (often written as $\sigma(x)$) to every number in a given range.

**Usage**

```r
numDivisorSieve(bound1, bound2 = NULL, namedVector = FALSE, nThreads = NULL)
```

**Arguments**

- `bound1`: Positive integer or numeric value.
- `bound2`: Positive integer or numeric value.
- `namedVector`: Logical flag. If TRUE, a named vector is returned. The default is FALSE.
- `nThreads`: Specific number of threads to be used. The default is NULL.

**Details**

Simple and efficient sieve that calculates the number of divisors for every number in a given range. This function is very useful when you need to calculate the number of divisors for many numbers. This algorithm benefits greatly from the fast integer division library `libdivide`. The following is from [https://libdivide.com/](https://libdivide.com/):

- "libdivide allows you to replace expensive integer divides with comparatively cheap multiplication and bitshifts. Compilers usually do this, but only when the divisor is known at compile time. libdivide allows you to take advantage of it at runtime. The result is that integer division can become faster - a lot faster."
numDivisorSieve

Value

Returns a named/unnamed integer vector

Note

The maximum allowed value is $2^{53} - 1$.

```
Description

The `Partitions` class is an S4-class that exposes C++ classes that provide access to iterators and other useful methods.

Slots

- `nextIter` Retrieve the **next** lexicographical result
- `nextNIter` Pass an integer `n` to retrieve the **next** `n` lexicographical results
- `nextRemaining` Retrieve all remaining lexicographical results
- `currIter` Returns the current iteration
- `startOver` Resets the iterator
- `sourceVector` View the source vector
- `summary` Returns a list of summary information about the iterator
- `front` Retrieve the **first** lexicographical result
- `back` Retrieve the **last** lexicographical result
- `randomAccess` Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.

showClass("Partitions")
```
partitionsCount

Description

Calculate the number of partitions/compositions of a vector chosen \( m \) at a time with or without replacement. Additionally, these functions can calculate the number of partitions of multisets.

Usage

partitionsCount(v, m = NULL, ...)  
compositionsCount(v, m = NULL, ...)

## Default S3 method:
partitionsCount(v, m = NULL, repetition = FALSE,  
freqs = NULL, target = NULL, ...)

## Default S3 method:
compositionsCount(v, m = NULL, repetition = FALSE,  
freqs = NULL, target = NULL, weak = FALSE, ...)

## S3 method for class 'table'
partitionsCount(v, m = NULL, target = NULL, ...)

## S3 method for class 'table'
compositionsCount(v, m = NULL, target = NULL, weak = FALSE, ...)

Arguments

v  
Source vector. If \( v \) is a positive integer, it will be converted to the sequence \( 1:v \). If \( v \) is a negative integer, it will be converted to the sequence \( v:-1 \). Only integer and numeric vectors are accepted.

m  
Width of the partition. If \( m = \text{NULL} \), the length will be determined by the partitioning case (e.g. When we are generating distinct partitions of \( n \), the width will be equal to the smallest \( m \) such that \( \text{sum}(1:m) >= n \)).

...  
Further arguments passed to methods.

repetition  
Logical value indicating whether partitions/compositions should be with or without repetition. The default is \text{FALSE}.

freqs  
A vector of frequencies used for producing all partitions of a multiset of \( v \). Each element of \( \text{freqs} \) represents how many times each element of the source vector, \( v \), is repeated. It is analogous to the \text{times} argument in \text{rep}. The default value is \text{NULL}.

target  
Number to be partitioned. If \text{NULL}, \text{max}(v) will be used.

weak  
(Compositions only) Logical flag indicating whether to allow terms of the sequence to be zero.
**partitionsGeneral**

**Value**

A numerical value representing the total number of partitions/compositions.

**Note**

When the number of results exceeds $2^{53} - 1$, a number of class bigz is returned.

**See Also**

`partitionsGeneral, compositionsGeneral`

**Examples**

```r
## Same interface as partitionsGeneral
partitionsCount(25, 5)
compositionsCount(25, 5, TRUE)
partitionsCount(15, 7, TRUE)
partitionsCount(25, 5, freqs = rep(2, 25))

## Return object of class 'bigz'
partitionsCount(2500, 15, TRUE)
compositionsCount(2500, 15, TRUE)
```

---

**Description**

The algorithms in RcppAlgos go beyond the traditional integer partition algorithms and can tackle a wide variety of cases.

- Efficient algorithms for partitioning numbers under various constraints:
  - Standard (with repetition)
  - Distinct
  - Restricted
  - Where each part has a specific multiplicity (i.e. when using freqs for multisets).
  - Arbitrary target and source vector (e.g. `partitionsGeneral(sample(1000, 20), 10, TRUE, target = 5000)``

- Produce results in parallel using the nThreads arguments.
- Alternatively, the arguments lower and upper make it possible to generate partitions/compositions in chunks allowing for parallelization via the parallel package.
- GMP support allows for exploration of cases where the number of partitions/compositions is large.
- The output is in lexicographical order.
partitionsGeneral

Usage

partitionsGeneral(v, m = NULL, ...)  
compositionsGeneral(v, m = NULL, ...)  

## Default S3 method:
partitionsGeneral  
  v, m = NULL, repetition = FALSE, freqs = NULL, target = NULL,  
  lower = NULL, upper = NULL, nThreads = NULL, tolerance = NULL, ...  

## Default S3 method:
compositionsGeneral  
  v, m = NULL, repetition = FALSE, freqs = NULL, target = NULL, weak = FALSE,  
  lower = NULL, upper = NULL, nThreads = NULL, tolerance = NULL, ...  

## S3 method for class 'table'
partitionsGeneral  
  v, m = NULL, target = NULL, lower = NULL,  
  upper = NULL, nThreads = NULL, tolerance = NULL, ...  

## S3 method for class 'table'
compositionsGeneral  
  v, m = NULL, target = NULL, weak = FALSE, lower = NULL,  
  upper = NULL, nThreads = NULL, tolerance = NULL, ...  

Arguments

v  
Source vector. If v is a positive integer, it will be converted to the sequence 1:v.  
If v is a negative integer, it will be converted to the sequence v:-1. Only integer  
and numeric vectors are accepted.

m  
Width of the partition. If m = NULL, the length will be determined by the partitioning case (e.g. When we are generating distinct partitions of n, the width will be equal to the smallest m such that sum(1:m) >= n).

...  
Further arguments passed to methods.

repetition  
Logical value indicating whether partitions/compositions should be with or without repetition. The default is FALSE.

freqs  
A vector of frequencies used for producing all partitions of a multiset of v. Each element of freqs represents how many times each element of the source vector, v, is repeated. It is analogous to the times argument in rep. The default value is NULL.

lower  
The lower bound. Partitions/compositions are generated lexicographically, thus utilizing this argument will determine which specific partition to start generating from (e.g. partitionsGeneral(15, 3, lower = 6) is equivalent to partitionsGeneral(15, 3)[6:partitionsCount(15, 3), ]). This argument along with upper is very useful for generating partitions/compositions in chunks allowing for easy parallelization.
partitionsGeneral

**upper**
The upper bound. Similar to lower, however this parameter allows the user to stop generation at a specific partition (e.g. partitionsGeneral(15, 3, upper = 5) is equivalent to partitionsGeneral(15, 3)[1:5, ])

**target**
Number to be partitioned. If NULL, max(v) will be used.

**weak**
(Compositions only) Logical flag indicating whether to allow terms of the sequence to be zero.

**nThreads**
Specific number of threads to be used. The default is NULL.

**tolerance**
A numeric value greater than or equal to zero. This parameter is utilized when a constraint is applied on a numeric vector. The default value is 0 when it can be determined that whole values are being utilized, otherwise it is sqrt(.Machine$double.eps) which is approximately 1.5e − 8. N.B. If the input vector is of type integer, this parameter will be ignored and strict equality will be enforced.

**Value**
A matrix is returned with each row containing a vector of length \(m\).

**Note**
- **nThreads** will be ignored in the following cases (i.e. Generating the \(n^{th}\) partition in these cases are currently unavailable):
  - With standard multisets. If zero is the only element with a non-trivial multiplicity, multithreading is possible (e.g. partitionsGeneral(0:100, freqs = c(100, rep(1, 100)), nThreads = 4)).
  - If the source vector is not isomorphic to 1:length(v) (e.g. \(v = c(1, 4, 6, 7, 8)\)).
- The maximum number of partitions/compositions that can be generated at one time is \(2^{31} - 1\). Utilizing lower and upper makes it possible to generate additional partitions/compositions.

partitionsIter  
Partition/Composition Iterator

Description

- Returns an iterator for iterating over partitions/compositions of a numbers.
- Supports random access via the [[ method.
- GMP support allows for exploration of cases where the number of partitions/compositions is large.
- Use the next methods to obtain results in lexicographical order.

Usage

partitionsIter(v, m = NULL, ...)  
compositionsIter(v, m = NULL, ...)

## Default S3 method:
partitionsIter(v, m = NULL, repetition = FALSE,  
freqs = NULL, target = NULL,  
nThreads = NULL, tolerance = NULL, ...)

## Default S3 method:
compositionsIter(v, m = NULL, repetition = FALSE, freqs = NULL,  
target = NULL, weak = FALSE, nThreads = NULL,  
tolerance = NULL, ...)

## S3 method for class 'table'
partitionsIter(  
v, m = NULL, target = NULL, nThreads = NULL, tolerance = NULL, ...
)

## S3 method for class 'table'
compositionsIter(  
v, m = NULL, target = NULL, weak = FALSE, nThreads = NULL, tolerance = NULL, ...
)
partitionsIter

Arguments

\( v \)  
Source vector. If \( v \) is a positive integer, it will be converted to the sequence \( 1:v \). If \( v \) is a negative integer, it will be converted to the sequence \( v:-1 \). Only integer and numeric vectors are accepted.

\( m \)  
Width of the partition. If \( m = \text{NULL} \), the length will be determined by the partitioning case (e.g. When we are generating distinct partitions of \( n \), the width will be equal to the smallest \( m \) such that \( \text{sum}(1:m) \geq n \)).

...  
Further arguments passed to methods.

\( \text{repetition} \)  
Logical value indicating whether partitions/compositions should be with or without repetition. The default is \( \text{FALSE} \).

\( \text{freqs} \)  
A vector of frequencies used for producing all partitions of a multiset of \( v \). Each element of \( \text{freqs} \) represents how many times each element of the source vector, \( v \), is repeated. It is analogous to the \( \text{times} \) argument in \( \text{rep} \). The default value is \( \text{NULL} \).

\( \text{target} \)  
Number to be partitioned. If \( \text{NULL} \), \( \text{max}(v) \) will be used.

\( \text{weak} \)  
(Compositions only) Logical flag indicating whether to allow terms of the sequence to be zero.

\( \text{nThreads} \)  
Specific number of threads to be used. The default is \( \text{NULL} \).

\( \text{tolerance} \)  
A numeric value greater than or equal to zero. This parameter is utilized when a constraint is applied on a numeric vector. The default value is 0 when it can be determined that whole values are being utilized, otherwise it is \( \text{sqrt}(\text{.Machine}$\text{double}$.eps) \) which is approximately \( 1.5e-8 \). N.B. If the input vector is of type integer, this parameter will be ignored and strict equality will be enforced.

Details

Once you initialize a new iterator, the following methods are available:

\( \text{nextIter} \)  
Retrieve the \textbf{next} lexicographical result

\( \text{nextNIter} \)  
Pass an integer \( n \) to retrieve the \textbf{next} \( n \) lexicographical results

\( \text{nextRemaining} \)  
Retrieve all remaining lexicographical results

\( \text{currIter} \)  
Returns the current iteration

\( \text{startOver} \)  
Resets the iterator

\( \text{sourceVector} \)  
View the source vector

\( \text{summary} \)  
Returns a list of summary information about the iterator

\( \text{front} \)  
Retrieve the \textbf{first} lexicographical result

\( \text{back} \)  
Retrieve the \textbf{last} lexicographical result

\([[]\)  
Random access method. Pass a single value or a vector of valid indices. If a single value is passed, the internal index of the iterator will be updated, however if a vector is passed the internal state will not change. GMP support allows for flexible indexing.

Value

- If \( \text{nextIter} \) is called, a vector is returned
- Otherwise, a matrix with \( m \) columns
Note

• If nThreads is utilized, it will only take effect if the number of elements requested is greater than some threshold (determined internally). E.g:

```r
serial <- partitionsIter(1000, 10)
multi <- partitionsIter(1000, 10, nThreads = 4)
fetch1e6 <- multi@nextNIter(1e6)  ## much faster than serial@nextNIter(1e6)
fetch1e3 <- multi@nextNIter(1e3)  ## only one thread used... same as serial@nextNIter(1e3)
```

library(microbenchmark)
microbenchmark(multi@nextNIter(1e6), serial@nextNIter(1e6))
microbenchmark(multi@nextNIter(1e3), serial@nextNIter(1e3))

• nThreads will be ignored in the following cases (i.e. Generating the $n^{th}$ partition in these cases are currently unavailable):
  – With standard multisets. If zero is the only element with a non-trivial multiplicity, multithreading is possible.
  – If the source vector is not isomorphic to 1:length(v)
• The maximum number of partitions/compositions that can be generated at one time is $2^{31} - 1$.

a@summary()
a[[c(1, 17, 3)]]
a@summary()
```
## Description

- Generate the rank (lexicographically) of partitions/compositions. These functions are the complement to `partitions/compositionsSample`. See the examples below.
- GMP support allows for exploration of partitions/compositions of vectors with many elements.

## Usage

```r
partitionsRank(..., v, repetition = FALSE, freqs = NULL, target = NULL)
```

```r
compositionsRank(..., v, repetition = FALSE, freqs = NULL,
                   target = NULL, weak = FALSE)
```

## Arguments

- `...` vectors or matrices to be ranked.
- `v` Source vector. If `v` is a positive integer, it will be converted to the sequence `1:v`. If `v` is a negative integer, it will be converted to the sequence `v:-1`. All atomic types are supported (See `is.atomic`).
- `repetition` Logical value indicating whether partitions/compositions should be with or without repetition. The default is `FALSE`.
- `freqs` A vector of frequencies used for producing all partitions of a multiset of `v`. Each element of `freqs` represents how many times each element of the source vector, `v`, is repeated. It is analogous to the `times` argument in `rep`. The default value is `NULL`.
- `target` Number to be partitioned. If `NULL`, `max(v)` will be used.
- `weak` (Compositions only) Logical flag indicating whether to allow terms of the sequence to be zero.

## Details

These algorithms rely on efficiently ranking the \( n^{th} \) lexicographical partition.

## Value

A vector of class `integer`, `numeric`, or `bigz` determined by the total number of partitions/compositions
partitionsSample

Note

v must be supplied.

partitionsSample, compositionsSample

Examples

mySamp = partitionsSample(30, 8, TRUE, n = 5, seed = 10, namedSample = TRUE)
myRank = partitionsRank(mySamp, v = 30, repetition = TRUE)
all.equal(as.integer(rownames(mySamp)), myRank)

Description

• Generate a specific (lexicographically) or random sample of partitions/compositions of a num-
  ber.
• Produce results in parallel using the Parallel or nThreads arguments.
• GMP support allows for exploration of cases where the number of partitions/compositions is
  large.

Usage

partitionsSample(v, m = NULL, ...)
compositionsSample(v, m = NULL, ...)

## Default S3 method:
partitionsSample(
  v, m = NULL, repetition = FALSE, freqs = NULL, target = NULL,
  n = NULL, sampleVec = NULL, seed = NULL,
  nThreads = NULL, namedSample = FALSE, ...
)
## Default S3 method:
compositionsSample(
  v, m = NULL, repetition = FALSE, freqs = NULL, target = NULL,
  weak = FALSE, n = NULL, sampleVec = NULL, seed = NULL,
partitionsSample

nThreads = NULL, namedSample = FALSE, ...
)

## S3 method for class 'table'
partitionsSample(
  v, m = NULL, target = NULL, n = NULL,
  sampleVec = NULL, seed = NULL, nThreads = NULL, namedSample = FALSE, ...
)

## S3 method for class 'table'
compositionsSample(
  v, m = NULL, target = NULL, weak = FALSE, n = NULL,
  sampleVec = NULL, seed = NULL, nThreads = NULL, namedSample = FALSE, ...
)

Arguments

v Source vector. If v is a positive integer, it will be converted to the sequence 1:v. If v is a negative integer, it will be converted to the sequence v:-1. Only integer and numeric vectors are accepted.

m Width of the partition. If m = NULL, the length will be determined by the partitioning case (e.g. When we are generating distinct partitions of n, the width will be equal to the smallest m such that sum(1:m) >= n).

... Further arguments passed to methods.

repetition Logical value indicating whether partitions/compositions should be with or without repetition. The default is FALSE.

dfrequents A vector of frequencies used for producing all partitions of a multiset of v. Each element of dfrequents represents how many times each element of the source vector, v, is repeated. It is analogous to the times argument in rep. The default value is NULL.

target Number to be partitioned. If NULL, max(v) will be used.

weak (Compositions only) Logical flag indicating whether to allow terms of the sequence to be zero.

n Number of partitions/compositions to return. The default is NULL.

sampleVec A vector of numbers representing the lexicographical partitions/compositions to return. Accepts vectors of class bigz as well as vectors of characters.

seed Random seed initialization. The default is NULL. N.B. If the gmp library is needed, this parameter must be set in order to have reproducible results (E.g set.seed() has no effect in these cases).

nThreads Specific number of threads to be used. The default is NULL.

namedSample Logical flag. If TRUE, rownames corresponding to the lexicographical partition, will be added to the returned matrix. The default is FALSE.

Details

These algorithms rely on efficiently generating the $n^{th}$ lexicographical partition. This is the process of unranking.
A matrix is returned with each row containing a vector of length \( m \).

Note

- `partitionsSample` is not available for the following cases:
  - With standard multisets. If zero is the only element with a non-trivial multiplicity, sampling is allowed (e.g. `partitionsSample(0:100, freqs = c(100, rep(1, 100)), n = 2)`).
  - If the source vector is not isomorphic to `1:length(v)` (e.g. \( v = c(1, 4, 6, 7, 8) \)).
- \( n \) and `sampleVec` cannot both be `NULL`.

## retrieve specific results (lexicographically)
partitionsCount(100, 10, TRUE, target = 500)
## [1] 175591757896
partitionsSample(100, 10, TRUE, target = 500,
               sampleVec = c(1, 1000, 175591757896))
```

---

Prime Counting Function \( \pi(x) \)

Description

Prime counting function for counting the prime numbers less than an integer, \( n \), using Legendre’s formula. It is based on the algorithm developed by Kim Walisch found here: kimwalisch/primecount.

Usage

```r
primeCount(n, nThreads = NULL)
```

Arguments

- \( n \) Positive number
- \( nThreads \) Specific number of threads to be used. The default is `NULL`. 
Details

Legendre’s Formula for counting the number of primes less than \( n \) makes use of the inclusion-exclusion principle to avoid explicitly counting every prime up to \( n \). It is given by:

\[
\pi(x) = \pi(\sqrt{x}) + \Phi(x, \sqrt{x}) - 1
\]

Where \( \Phi(x, a) \) is the number of positive integers less than or equal to \( x \) that are relatively prime to the first \( a \) primes (i.e. not divisible by any of the first \( a \) primes). It is given by the recurrence relation (\( p_a \) is the \( a \)th prime (e.g. \( p_4 = 7 \))):

\[
\Phi(x, a) = \Phi(x, a - 1) + \Phi(x/p_a, a - 1)
\]

This algorithm implements five modifications developed by Kim Walisch for calculating \( \Phi(x, a) \) efficiently.

1. Cache results of \( \Phi(x, a) \)
2. Calculate \( \Phi(x, a) \) using \( \Phi(x, a) = (x/pp) \ast \phi(pp) + \Phi(x \mod pp, a) \) if \( a \leq 6 \)
   * \( pp = 2 \ast 3 \ast \ldots \ast \text{prime[a]} \)
   * \( \phi(pp) = (2 - 1) \ast (3 - 1) \ast \ldots \ast (\text{prime[a]} - 1) \) (i.e. Euler’s totient function)
3. Calculate \( \Phi(x, a) \) using \( \pi(x) \) lookup table
4. Calculate all \( \Phi(x, a) = 1 \) upfront
5. Stop recursion at 6 if \( \sqrt{x} \geq 13 \) or \( \pi(\sqrt{x}) \) instead of 1

Value

Whole number representing the number of prime numbers less than or equal to \( n \).

Note

The maximum value of \( n \) is \( 2^{53} - 1 \)

```

---

**primeFactorize**  
**Vectorized Prime Factorization**

**Description**

Implementation of Pollard’s rho algorithm for generating the prime factorization. The algorithm is based on the “factorize.c” source file from the gmp library found here [https://gmplib.org](https://gmplib.org).

**Usage**

```r
primeFactorize(v, namedList = FALSE, nThreads = NULL)
```

**Arguments**

- `v` Vector of integers or numeric values. Non-integral values will be cured to whole numbers.
- `namedList` Logical flag. If `TRUE` and the `length(v) > 1`, a named list is returned. The default is `FALSE`.
- `nThreads` Specific number of threads to be used. The default is `NULL`.

**Details**

As noted in the Description section above, this algorithm is based on the "factorize.c" source code from the gmp library. Much of the code in RcppAlgos::primeFactorize is a straightforward translation from multiple precision C data types to standard C++ data types. A crucial part of the algorithm’s efficiency is based on quickly determining primality, which is easily computed with gmp. However, with standard C++, this is quite challenging. Much of the research for RcppAlgos::primeFactorize was focused on developing an algorithm that could accurately and efficiently compute primality.

For more details, see the documentation for `isPrimeRcpp`.

**Value**

- Returns an unnamed vector if `length(v) == 1` regardless of the value of `namedList`. If `v < 2^{31}`, the class of the returned vector will be integer, otherwise the class will be numeric.
- If `length(v) > 1`, a named/unnamed list of vectors will be returned. If `max(bound1, bound2) < 2^{31}`, the class of each vector will be integer, otherwise the class will be numeric.
primeFactorizeSieve

Note
The maximum value for each element in \( v \) is \( 2^{53} - 1 \).

primeFactorize(10^8)

## Or get the prime factorization of many numbers
set.seed(29)
myVec <- sample(-1000000:1000000, 1000)
system.time(pFacs <- primeFactorize(myVec))

## Return named list
pFacsWithNames <- primeFactorize(myVec, namedList = TRUE)

## Using nThreads
system.time(primeFactorize(myVec, nThreads = 2))
```

---

primeFactorizeSieve

Generate Prime Factorization for Numbers in a Range

Description
Generates the prime factorization of all numbers between `bound1` and `bound2` (if supplied) or all numbers up to `bound1`.

Usage
primeFactorizeSieve(bound1, bound2 = NULL, namedList = FALSE, nThreads = NULL)
Arguments

- **bound1**: Positive integer or numeric value.
- **bound2**: Positive integer or numeric value.
- **namedList**: Logical flag. If TRUE, a named list is returned. The default is FALSE.
- **nThreads**: Specific number of threads to be used. The default is NULL.

Details

This function is useful when many prime factorizations are needed. Instead of generating the prime factorization on the fly, one can reference the indices/names of the generated list.

This algorithm benefits greatly from the fast integer division library 'libdivide'. The following is from https://libdivide.com/:

- "libdivide allows you to replace expensive integer divides with comparatively cheap multiplication and bitshifts. Compilers usually do this, but only when the divisor is known at compile time. libdivide allows you to take advantage of it at runtime. The result is that integer division can become faster - a lot faster."

Value

Returns a named/unnamed list of integer vectors if max(bound1, bound2) < 2^{31}, or a list of numeric vectors otherwise.

Note

The maximum value for either of the bounds is 2^{53} – 1.

primeFactorizeSieve(27, 30, namedList = TRUE)

## Using nThreads
system.time(primeFactorizeSieve(1e4, 5e4, nThreads = 2))
```

primeSieve Generate Prime Numbers

Description

Implementation of the segmented sieve of Eratosthenes with wheel factorization. Generates all prime numbers between `bound1` and `bound2` (if supplied) or all primes up to `bound1`. See this stackoverflow post for an analysis on prime number generation efficiency in R: Generate a list of primes up to a certain number.

The fundamental concepts of this algorithm are based off of the implementation by Kim Walisch found here: kimwalisch/primesieve.

Usage

`primeSieve(bound1, bound2 = NULL, nThreads = NULL)`

Arguments

- `bound1`: Positive integer or numeric value.
- `bound2`: Positive integer or numeric value.
- `nThreads`: Specific number of threads to be used. The default is NULL.
Details
At the heart of this algorithm is the traditional sieve of Eratosthenes (i.e. given a prime \( p \), mark all multiples of \( p \) as composite), however instead of sieving the entire interval, we only consider small sub-intervals. The benefits of this method are two fold:

1. Reduction of the space complexity from \( O(n) \), for the traditional sieve, to \( O(\sqrt{n}) \)
2. Reduction of cache misses

The latter is of particular importance as cache memory is much more efficient and closer in proximity to the CPU than main memory. Reducing the size of the sieving interval allows for more effective utilization of the cache, which greatly impacts the overall efficiency.

Another optimization over the traditional sieve is the utilization of wheel factorization. With the traditional sieve of Eratosthenes, you typically check every odd index of your logical vector and if the value is true, you have found a prime. With wheel factorization using the first four primes (i.e. 2, 3, 5, and 7) to construct your wheel (i.e. 210 wheel), you only have to check indices of your logical vector that are coprime to 210 (i.e. the product of the first four primes). As an example, with \( n = 10000 \) and a 210 wheel, you only have to check 2285 indices vs. 5000 with the classical implementation.

Value

Returns an integer vector if \( \max(\text{bound1}, \text{bound2}) < 2^{31} \), or a numeric vector otherwise.

Note

- It does not matter which bound is larger as the resulting primes will be between \( \min(\text{bound1}, \text{bound2}) \) and \( \max(\text{bound1}, \text{bound2}) \) if \( \text{bound2} \) is provided.
- The maximum value for either of the bounds is \( 2^{53} - 1 \).
