Package ‘mcmc’

February 16, 2020

Version 0.9-6.1
Date 2019-03-09
Title Markov Chain Monte Carlo
Author Charles J. Geyer <charlie@stat.umn.edu> and Leif T. Johnson
<ltjohnson@google.com>
Maintainer ORPHANED
Depends R (>= 3.0.2)
Imports stats
Suggests xtable, Iso
ByteCompile TRUE
Description Simulates continuous distributions of random vectors using
Markov chain Monte Carlo (MCMC). Users specify the distribution by an
R function that evaluates the log unnormalized density. Algorithms
are random walk Metropolis algorithm (function metrop), simulated
tempering (function temper), and morphometric random walk Metropolis
(Johnson and Geyer, 2012, <doi:10.1214/12-AOS1048>,
function morph.metrop),
which achieves geometric ergodicity by change of variable.

Description
Like it says

Usage
data(foo)

Format
A data frame with variables

x1 quantitative predictor.
x2 quantitative predictor.
x3 quantitative predictor.
y Bernoulli response.

Examples
library(mcmc)
data(foo)
out <- glm(y ~ x1 + x2 + x3, family = binomial, data = foo)
summary(out)
**initseq**  

### Initial Sequence Estimators

**Description**

**Usage**

```r
initseq(x)
```

**Arguments**

- `x` a numeric vector that is a scalar-valued functional of a reversible Markov chain.

**Details**

Let

\[ \gamma_k = \text{cov}(X_i, X_{i+k}) \]

considered as a function of the lag \( k \) be the autocovariance function of the input time series. Define

\[ \Gamma_k = \gamma_{2k} + \gamma_{2k+1} \]

the sum of consecutive pairs of autocovariances. Then Theorem 3.1 in Geyer (1992) says that \( \Gamma_k \) considered as a function of \( k \) is strictly positive, strictly decreasing, and strictly convex, assuming the input time series is a scalar-valued functional of a reversible Markov chain. All of the MCMC done by this package is reversible. This \texttt{R} function estimates the “big gamma” function, \( \Gamma_k \) considered as a function of \( k \), subject to three different constraints, (1) nonnegative, (2) nonnegative and nonincreasing, and (3) nonnegative, nonincreasing, and convex. It also estimates the variance in the Markov chain central limit theorem (CLT)

\[
\gamma_0 + 2 \sum_{k=1}^{\infty} \gamma_k = -\gamma_0 + 2 \sum_{k=0}^{\infty} \Gamma_k
\]

**Note:** The batch means provided by \texttt{metrop} are also scalar functionals of a reversible Markov chain. Thus these initial sequence estimators applied to the batch means give valid standard errors for the mean of the batch means even when the batch length is too short to provide a valid estimate of asymptotic variance. One does, of course, have to multiply the asymptotic variance of the batch means by the batch length to get the asymptotic variance for the unbatched chain.

**Value**

a list containing the following components:

- `gamma0` the scalar \( \gamma_0 \), the marginal variance of \( x \).
- `Gamma.pos` the vector \( \Gamma \), estimated so as to be nonnegative, where, as always, \texttt{R} uses one-origin indexing so `Gamma.pos[1]` is \( \Gamma_0 \).
Gamma.dec  the vector \( \Gamma \), estimated so as to be nonnegative and nonincreasing, where, as always, \( R \) uses one-origin indexing so \( \text{Gamma.dec}[1] \) is \( \Gamma_0 \).

Gamma.con  the vector \( \Gamma \), estimated so as to be nonnegative and nonincreasing and convex, where, as always, \( R \) uses one-origin indexing so \( \text{Gamma.con}[1] \) is \( \Gamma_0 \).

var.pos  the scalar \( -\gamma_0 + 2 \times \text{sum(Gamma.pos)} \), which is the asymptotic variance in the Markov chain CLT. Divide by \( \text{length(x)} \) to get the approximate variance of the sample mean of \( x \).

var.dec  the scalar \( -\gamma_0 + 2 \times \text{sum(Gamma.dec)} \), which is the asymptotic variance in the Markov chain CLT. Divide by \( \text{length(x)} \) to get the approximate variance of the sample mean of \( x \).

var.con  the scalar \( -\gamma_0 + 2 \times \text{sum(Gamma.con)} \), which is the asymptotic variance in the Markov chain CLT. Divide by \( \text{length(x)} \) to get the approximate variance of the sample mean of \( x \).

**Bugs**

Not precisely a bug, but \( \text{var.pos} \), \( \text{var.dec} \), and \( \text{var.con} \) can be negative. This happens only when the chain is way too short to estimate the variance, and even then rarely. But it does happen.

## Not run:
plot(seq(along = out$Gamma.pos) - 1, out$Gamma.pos,
xlab = "k", ylab = expression(Gamma[k]), type = "l")
lines(seq(along = out$Gamma.dec) - 1, out$Gamma.dec, col = "red")
lines(seq(along = out$Gamma.con) - 1, out$Gamma.con, col = "blue")
## End(Not run)

# asymptotic 95% confidence interval for mean of x
mean(x) + c(-1, 1) * qnorm(0.975) * sqrt(out$var.con / length(x))
# estimated asymptotic variance
out$var.con
# theoretical asymptotic variance
(1 + rho) / (1 - rho) * 1 / (1 - rho^2)
# illustrating use with batch means
bm <- apply(matrix(x, nrow = 5), 2, mean)
initseq(bm)$var.con * 5
```
**logit**  

*Simulated logistic regression data.*

**Description**

Like it says

**Usage**

```r
data(logit)
```

**Format**

A data frame with variables

- `x1` quantitative predictor.
- `x2` quantitative predictor.
- `x3` quantitative predictor.
- `x4` quantitative predictor.
- `y` Bernoulli response.

**Examples**

```r
library(mcmc)
data(logit)
out <- glm(y ~ x1 + x2 + x3 + x4, family = binomial, data = logit)
summary(out)
```

**metrop**  

*Metropolis Algorithm*

**Description**

Markov chain Monte Carlo for continuous random vector using a Metropolis algorithm.

**Usage**

```r
metrop(obj, initial, nbatch, blen = 1, nspac = 1, scale = 1, outfun,
debug = FALSE, ...)
```

## S3 method for class 'function'

```r
metrop(obj, initial, nbatch, blen = 1, nspac = 1,
  scale = 1, outfun, debug = FALSE, ...)
```

## S3 method for class 'metropolis'

```r
metrop(obj, initial, nbatch, blen = 1, nspac = 1,
  scale = 1, outfun, debug = FALSE, ...)
```
Arguments

**obj**
Either an R function or an object of class "metropolis" from a previous invocation of this function.

If a function, it evaluates the log unnormalized probability density of the desired equilibrium distribution of the Markov chain. Its first argument is the state vector of the Markov chain. Other arguments arbitrary and taken from the ... arguments of this function. It should return -Inf for points of the state space having probability zero under the desired equilibrium distribution. See also Details andWarning.

If an object of class "metropolis", any missing arguments (including the log unnormalized density function) are taken from this object. Also initial is ignored and the initial state of the Markov chain is the final state from the run recorded in obj.

**initial**
a real vector, the initial state of the Markov chain. Must be feasible, see Details. Ignored if obj is of class "metropolis".

**nbatch**
the number of batches.

**blen**
the length of batches.

**nspac**
the spacing of iterations that contribute to batches.

**scale**
controls the proposal step size. If scalar or vector, the proposal is \( x + \text{scale} \times z \) where \( x \) is the current state and \( z \) is a standard normal random vector. If matrix, the proposal is \( x + \text{scale} \times z \).

**outfun**
controls the output. If a function, then the batch means of \( \text{outfun}(\text{state},...) \) are returned. If a numeric or logical vector, then the batch means of \( \text{state}[\text{outfun}] \) (if this makes sense). If missing, the the batch means of \( \text{state} \) are returned.

**debug**
if TRUE extra output useful for testing.

... additional arguments for obj or outfun.

Details

Runs a “random-walk” Metropolis algorithm, terminology introduced by Tierney (1994), with multivariate normal proposal producing a Markov chain with equilibrium distribution having a specified unnormalized density. Distribution must be continuous. Support of the distribution is the support of the density specified by argument obj. The initial state must satisfy \( \text{obj}(\text{state},...) > -\text{Inf} \).

Description of a complete MCMC analysis (Bayesian logistic regression) using this function can be found in the vignette vignette(“demo”, "mcmc”).

Suppose the function coded by the log unnormalized function (either obj or obj$lud) is actually a log unnormalized density, that is, if \( w \) denotes that function, then \( e^w \integrates \) to some value strictly between zero and infinity. Then the metrop function always simulates a reversible, Harris ergodic Markov chain having the equilibrium distribution with this log unnormalized density. The chain is not guaranteed to be geometrically ergodic. In fact it cannot be geometrically ergodic if the tails of the log unnormalized density are sufficiently heavy. The morph.metrop function deals with this situation.
Value

an object of class "mcmc", subclass "metropolis", which is a list containing at least the following components:

accept  fraction of Metropolis proposals accepted.
batch  nbatch by p matrix, the batch means, where p is the dimension of the result of
       outfun if outfun is a function, otherwise the dimension of state[outfun] if
       that makes sense, and the dimension of state when outfun is missing.
accept.batch  a vector of length nbatch, the batch means of the acceptances.
initial  value of argument initial.
final  final state of Markov chain.
initial.seed  value of .Random.seed before the run.
final.seed  value of .Random.seed after the run.
time  running time of Markov chain from system.time().
lud  the function used to calculate log unnormalized density, either obj or obj$lud
       from a previous run.
nbatch  the argument nbatch or obj$nbatch.
blen  the argument blen or obj$blen.
nspac  the argument nspac or obj$nspac.
outfun  the argument outfun or obj$outfun.

Description of additional output when debug = TRUE can be found in the vignette debug (../doc/debug.pdf).

Warning

If outfun is missing or not a function, then the log unnormalized density can be defined without a...argument and that works fine. One can define it starting ludfun <- function(state) and that works or ludfun <- function(state, foo, bar), where foo and bar are supplied as additional arguments to metrop.

If outfun is a function, then both it and the log unnormalized density function can be defined without ...arguments if they have exactly the same arguments list and that works fine. Otherwise it doesn’t work. Define these functions by

ludfun <- function(state, foo)
outfun <- function(state, bar)

and you get an error about unused arguments. Instead define these functions by

ludfun <- function(state, foo, ...)
outfun <- function(state, bar, ...)

and supply foo and bar as additional arguments to metrop, and that works fine.

In short, the log unnormalized density function and outfun need to have ...in their arguments list to be safe. Sometimes it works when ...is left out and sometimes it doesn’t.
Of course, one can avoid this whole issue by always defining the log unnormalized density function and `outfun` to have only one argument `state` and use global variables (objects in the `R` global environment) to specify any other information these functions need to use. That too follows the `R` way. But some people consider that bad programming practice.

A third option is to define either or both of these functions using a function factory. This is demonstrated in the vignette for this package named `demo`, which is shown by `vignette("demo","mcmc")`.

**Philosophy of MCMC**

This function follows the philosophy of MCMC explained in the introductory chapter of the *Handbook of Markov Chain Monte Carlo* (Geyer, 2011).

This function automatically does batch means in order to reduce the size of output and to enable easy calculation of Monte Carlo standard errors (MCSE), which measure error due to the Monte Carlo sampling (not error due to statistical sampling — MCSE gets smaller when you run the computer longer, but statistical sampling variability only gets smaller when you get a larger data set). All of this is explained in the package vignette `vignette("demo","mcmc")` and in Section 1.10 of Geyer (2011).

This function does not apparently do “burn-in” because this concept does not actually help with MCMC (Geyer, 2011, Section 1.11.4) but the re-entrant property of this function does allow one to do “burn-in” if one wants. Assuming `ludfun`, `start.value`, `scale` have been already defined and are, respectively, an `R` function coding the log unnormalized density of the target distribution, a valid state of the Markov chain, and a useful scale factor,

```r
out <- metrop(ludfun, start.value, nbatch = 1, blen = 1e5, scale = scale)
out <- metrop(out, nbatch = 100, blen = 1000)
```

throws away a run of 100 thousand iterations before doing another run of 100 thousand iterations that is actually useful for analysis, for example,

```r
apply(out$batch, 2, mean)
apply(out$batch, 2, sd) / sqrt(out$nbatch)
```

give estimates of posterior means and their MCSE assuming the batch length (here 1000) was long enough to contain almost all of the significant autocorrelation (see Geyer, 2011, Section 1.10, for more on MCSE). The re-entrant property of this function (the second run starts where the first one stops) assures that this is really “burn-in”.

The re-entrant property allows one to do very long runs without having to do them in one invocation of this function.

```r
out2 <- metrop(out)
out3 <- metrop(out2)
batch <- rbind(out$batch, out2$batch, out3$batch)
```

produces a result as if the first run had been three times as long.
Tuning

The scale argument must be adjusted so that the acceptance rate is not too low or too high to get reasonable performance. The rule of thumb is that the acceptance rate should be about 25%. But this recommendation (Gelman, et al., 1996) is justified by analysis of a toy problem (simulating a spherical multivariate normal distribution) for which MCMC is unnecessary. There is no reason to believe this is optimal for all problems (if it were optimal, a stronger theorem could be proved). Nevertheless, it is clear that at very low acceptance rates the chain makes little progress (because in most iterations it does not move) and that at very high acceptance rates the chain also makes little progress (because unless the log unnormalized density is nearly constant, very high acceptance rates can only be achieved by very small values of scale so the steps the chain takes are also very small).

Even in the Gelman, et al. (1996) result, the optimal rate for spherical multivariate normal depends on dimension. It is 44% for $d = 1$ and 23% for $d = \infty$. Geyer and Thompson (1995) have an example, admittedly for simulated tempering (see temper) rather than random-walk Metropolis, in which no acceptance rate less than 70% produces an ergodic Markov chain. Thus 25% is merely a rule of thumb. We only know we don’t want too high or too low. Probably 1% or 99% is very inefficient.

Examples

h <- function(x) if (all(x >= 0) && sum(x) <= 1) return(1) else return(-Inf)
out <- metrop(h, rep(0, 5), 1000)
out$accept
# acceptance rate too low
out <- metrop(out, scale = 0.1)
out$accept
t.test(out$accept.batch)$conf.int
# acceptance rate o. k. (about 25 percent)
plot(out$batch[, 1])
# but run length too short (few excursions from end to end of range)
out <- metrop(out, nbatch = 1e4)
```
out$accept
plot(out$batch[, 1])
hist(out$batch[, 1])
acf(out$batch[, 1], lag.max = 250)
# looks like batch length of 250 is perhaps OK
out <- metrop(out, blen = 250, nbatch = 100)
apply(out$batch, 2, mean) # Monte Carlo estimates of means
apply(out$batch, 2, sd) / sqrt(out$nbatch) # Monte Carlo standard errors
t.test(out$accept$batch)$conf.int
acf(out$batch[, 1]) # appears that blen is long enough
```

---

**morph**

### Variable Transformation

**Description**

Utility functions for variable transformation.

**Usage**

```r
morph(b, r, p, center)
morph.identity()
```

**Arguments**

- **b**
  - Positive real number. May be missing.
- **r**
  - Non-negative real number. May be missing. If `p` is specified, `r` defaults to 0.
- **p**
  - Real number strictly greater than 2. May be missing. If `r` is specified, `p` defaults to 3.
- **center**
  - Real scalar or vector. May be missing. If `center` is a vector it should be the same length of the state of the Markov chain, `center` defaults to 0

**Details**

The `morph` function facilitates using variable transformations by providing functions to (using $X$ for the original random variable with the pdf $f_X$, and $Y$ for the transformed random variable with the pdf $f_Y$):

- Calculate the log unnormalized probability density for $Y$ induced by the transformation.
- Transform an arbitrary function of $X$ to a function of $Y$.
- Transform values of $X$ to values of $Y$.
- Transform values of $Y$ to values of $X$ (the inverse transformation).

for a select few transformations.

`morph.identity` implements the identity transformation, $Y = X$. 

---
The parameters r, p, b and center specify the transformation function. In all cases, center gives the center of the transformation, which is the value c in the equation
\[ Y = f(X - c). \]

If no parameters are specified, the identity transformation, \( Y = X \), is used.

The parameters r, p and b specify a function \( g \), which is a monotonically increasing bijection from the non-negative reals to the non-negative reals. Then
\[ f(X) = g(|X|) \frac{X}{|X|} \]
where \(|X|\) represents the Euclidean norm of the vector \( X \). The inverse function is given by
\[ f^{-1}(Y) = g^{-1}(|Y|) \frac{Y}{|Y|}. \]

The parameters r and p are used to define the function
\[ g_1(x) = x + (x - r)pI(x > r) \]
where \( I(\cdot) \) is the indicator function. We require that \( r \) is non-negative and \( p \) is strictly greater than 2. The parameter b is used to define the function
\[ g_2(x) = (e^{bx} - e/3)I(x > \frac{1}{b}) + (x^3b^3e/6 + xbe/2)I(x \leq \frac{1}{b}) \]
We require that \( b \) is positive.

The parameters r, p and b specify \( f^{-1} \) in the following manner:

- If one or both of r and p is specified, and b is not specified, then
  \[ f^{-1}(X) = g_1(|X|) \frac{X}{|X|}. \]
  If only r is specified, \( p = 3 \) is used. If only p is specified, \( r = 0 \) is used.
- If only b is specified, then
  \[ f^{-1}(X) = g_2(|X|) \frac{X}{|X|}. \]
- If one or both of r and p is specified, and b is also specified, then
  \[ f^{-1}(X) = g_2(g_1(|X|)) \frac{X}{|X|}. \]

Value

- a list containing the functions
  - \( \text{outfun(f)} \), a function that operates on functions. \( \text{outfun(f)} \) returns the function \( \text{function(state, \ldots)} \ f(\text{inverse(state), \ldots}) \).
  - \( \text{inverse} \), the inverse transformation function.
• transform, the transformation function.
• lud, a function that operates on functions. As input, lud takes a function that calculates a log unnormalized probability density, and returns a function that calculates the log unnormalized density by transforming a random variable using the transform function. lud(f) = function(state,...) f(inverse(state),...) + log.jacobian(state), where log.jacobian represents the function that calculate the log Jacobian of the transformation. log.jacobian is not returned.

Warning
The equations for the returned transform function (see below) do not have a general analytical solution when p is not equal to 3. This implementation uses numerical approximation to calculate transform when p is not equal to 3. If computation speed is a factor, it is advisable to use p=3. This is not a factor when using morph.metrop, as transform is only called once during setup, and not at all while running the Markov chain.

morph.metrop

Examples

# use an exponential transformation, centered at 100.
b1 <- morph(b=1, center=100)
# original log unnormalized density is from a t distribution with 3
degrees of freedom, centered at 100.
lud.transformed <- b1$lud(function(x) dt(x - 100, df=3, log=TRUE))
d.transformed <- Vectorize(function(x) exp(lud.transformed(x)))
## Not run:
curve(d.transformed, from=-3, to=3, ylab="Induced Density")
## End(Not run)
Arguments

obj      see metrop.
initial  see metrop.
nbatch   see metrop.
blen     see metrop.
nspac    see metrop.
scale    see metrop.
outfun   unlike for metrop must be a function or missing; if missing the identity function, function(x) x, is used.
debug    see metrop.
morph    morph object used for transformations. See morph.
...      see metrop.

Details

morph.metrop implements morphometric methods for Markov chains. The caller specifies a log unnormalized probability density and a transformation. The transformation specified by the morph parameter is used to induce a new log unnormalized probability density, a Metropolis algorithm is run for the induced density. The Markov chain is transformed back to the original scale. Running the Metropolis algorithm for the induced density, instead of the original density, can result in a Markov chain with better convergence properties. For more details see Johnson and Geyer (submitted). Except for morph, all parameters are passed to metrop, transformed when necessary. The scale parameter is not transformed.

If $X$ is a real vector valued continuous random variable, and $Y = f(X)$ where $f$ is a diffeomorphism, then the pdf of $Y$ is given by

$$f_Y(y) = f_X(f^{-1}(y))|\nabla f^{-1}(y)|$$

where $f_X$ is the pdf of $X$ and $\nabla f^{-1}$ is the Jacobian of $f^{-1}$. Because $f$ is a diffeomorphism, a Markov chain for $f_Y$ may be transformed into a Markov chain for $f_X$. Furthermore, these Markov chains are isomorphic (Johnson and Geyer, submitted) and have the same convergence rate. The morph variable provides a diffeomorphism, morph.metrop uses this diffeomorphism to induce the log unnormalized density, $\log f_Y$ based on the user supplied log unnormalized density, $\log f_X$. morph.metrop runs a Metropolis algorithm for $\log f_Y$ and transforms the resulting Markov chain into a Markov chain for $f_X$. The user accessible output components are the same as those that come from metrop, see the documentation for metrop for details.

Subsequent calls of morph.metrop may change to the transformation by specifying a new value for morph.

Any of the other parameters to morph.metrop may also be modified in subsequent calls. See metrop for more details.

The general idea is that a random-walk Metropolis sampler (what metrop does) will not be geometrically ergodic unless the tails of the unnormalized density decrease superexponentially fast (so the tails of the log unnormalized density decrease faster than linearly). It may not be geometrically ergodic even then (see Johnson and Geyer, submitted, for the complete theory). The transformations
used by this function (provided by `morph`) can produce geometrically ergodic chains when the tails of the log unnormalized density are too light for `metrop` to do so.

When the tails of the unnormalized density are exponentially light but not superexponentially light (so the tails of the log unnormalized density are asymptotically linear, as in the case of exponential family models when conjugate priors are used, for example logistic regression, Poisson regression with log link, or log-linear models for categorical data), one should use `morph` with `b = 0` (the default), which produces a transformation of the form $g_1$ in the notation used in the details section of the help for `morph`. This will produce a geometrically ergodic sampler if other features of the log unnormalized density are well behaved. For example it will do so for the exponential family examples mentioned above. (See Johnson and Geyer, submitted, for the complete theory.)

The transformation $g_1$ behaves like a shift transformation on a ball of radius $r$ centered at `center`, so these arguments to `morph` should be chosen so that a sizable proportion of the probability under the original (untransformed) unnormalized density is contained in this ball. This function will work when $r = 0$ and `center = 0` (the defaults) are used, but may not work as well as when $r$ and `center` are well chosen.

When the tails of the unnormalized density are not exponentially light (so the tails of the log unnormalized density decrease sublinearly, as in the case of univariate and multivariate t distributions), one should use `morph` with $r > 0$ and $p = 3$, which produces a transformation of the form $g_2$ composed with $g_1$ in the notation used in the details section of the help for `morph`. This will produce a geometrically ergodic sampler if other features of the log unnormalized density are well behaved. For example it will do so for the $t$ examples mentioned above. (See Johnson and Geyer, submitted, for the complete theory.)

Value

an object of class `mcmc`, subclass `morph.metropolis`. This object is a list containing all of the elements from an object returned by `metrop`, plus at least the following components:

- `morph` the morph object used for the transformations.
- `morph.final` the final state of the Markov chain on the transformed scale.

`metrop`, `morph`.

Examples

```r
out <- morph.metrop(function(x) dt(x, df=3, log=TRUE), 0, blen=100, nbatch=100, morph=morph(b=1))
# change the transformation.
out <- morph.metrop(out, morph=morph(b=2))
out$accept
# accept rate is high, increase the scale.
out <- morph.metrop(out, scale=4)
```
olbm

# close to 0.20 is about right.
out$accept

olbm

Overlapping Batch Means

Description

Variance of sample mean of time series calculated using overlapping batch means.

Usage

olbm(x, batch.length, demean = TRUE)

Arguments

x

a matrix or time series object. Each column of x is treated as a scalar time series.

batch.length

length of batches.

demean

when demean = TRUE (the default) the sample mean is subtracted from each batch mean when estimating the variance. Using demean = FALSE would essentially assume the true mean is known to be zero, which might be useful in a toy problem where the answer is known.

Value

The estimated variance of the sample mean.

Examples

h <- function(x) if (all(x >= 0) && sum(x) <= 1) return(1) else return(-Inf)
out <- metrop(h, rep(0, 5), 1000)
out <- metrop(out, scale = 0.1)
out <- metrop(out, nbatch = 1e4)
foo <- olbm(out$batch, 150)
# monte carlo estimates (true means are same by symmetry)
apply(out$batch, 2, mean)
# monte carlo standard errors (true s. d. are same by symmetry)
sqrt(diag(foo))
# check that batch length is reasonable
acf(out$batch, lag.max = 200)
Description

Markov chain Monte Carlo (MCMC) for continuous random vectors using parallel or serial tempering, the latter also called umbrella sampling and simulated tempering. The chain simulates $k$ different distributions on the same state space. In parallel tempering, all the distributions are simulated in each iteration. In serial tempering, only one of the distributions is simulated (a random one). In parallel tempering, the state is a $k \times p$ matrix, each row of which is the state for one of the distributions. In serial tempering the state of the Markov chain is a pair $(i, x)$, where $i$ is an integer between 1 and $k$ and $x$ is a vector of length $p$. This pair is represented as a single real vector $c(i, x)$. The variable $i$ says which distribution $x$ is a simulation for.

Usage

```r
temper(obj, initial, neighbors, nbatch, blen = 1, nspac = 1, scale = 1,
     outfun, debug = FALSE, parallel = FALSE, ...)

## S3 method for class 'function'
temper(obj, initial, neighbors, nbatch,
     blen = 1, nspac = 1, scale = 1,
     outfun, debug = FALSE, parallel = FALSE, ...)

## S3 method for class 'tempering'
temper(obj, initial, neighbors, nbatch,
     blen = 1, nspac = 1, scale = 1,
     outfun, debug = FALSE, parallel = FALSE, ...)
```

Arguments

- `obj` either an R function or an object of class "tempering" from a previous run. If a function, it should evaluate the log unnormalized density $\log h(i, x)$ of the desired equilibrium distribution of the Markov chain for serial tempering (the same function is used for both serial and parallel tempering, see Details below for further explanation). If an object of class "tempering", the log unnormalized density function is `obj$lud`, and missing arguments of `temper` are obtained from the corresponding elements of `obj`. The first argument of the log unnormalized density function is the is an R vector $c(i, x)$, where $i$ says which distribution $x$ is supposed to be a simulation for. Other arguments are arbitrary and taken from the ... arguments of `temper`. The log unnormalized density function should return $-\text{Inf}$ in regions of the state space having probability zero.

- `initial` for serial tempering, a real vector $c(i, x)$ as described above. For parallel tempering, a real $k \times p$ matrix as described above. In either case, the initial state of the Markov chain. Ignored if `obj` has class "tempering".
temper

neighbors a logical symmetric matrix of dimension k by k. Elements that are TRUE indicate jumps or swaps attempted by the Markov chain. Ignored if obj has class "tempering".

nbatch the number of batches.

blen the length of batches.

nspac the spacing of iterations that contribute to batches.

scale controls the proposal step size for real elements of the state vector. For serial tempering, proposing a new value for the x part of the state (i, x). For parallel tempering, proposing a new value for the x_i part of the state (x_1, ..., x_k). In either case, the proposal is a real vector of length p. If scalar or vector, the proposal is x + scale * z where x is the part x or x_i of the state the proposal may replace. If matrix, the proposal is x + scale %x% z. If list, the length must be k, and each element must be scalar, vector, or matrix, and operate as described above. The i-th component of the list is used to update x when the state is (i, x) or x_i otherwise.

outfun controls the output. If a function, then the batch means of outfun(state,...) are returned. The argument state is like the argument initial of this function. If missing, the batch means of the real part of the state vector or matrix are returned, and for serial tempering the batch means of a multivariate Bernoulli indicating the current component are returned.

debug if TRUE extra output useful for testing.

parallel if TRUE does parallel tempering, if FALSE does serial tempering. Ignored if obj has class "tempering".

... additional arguments for obj or outfun.

Details

Serial tempering simulates a mixture of distributions of a continuous random vector. The number of components of the mixture is k, and the dimension of the random vector is p. Denote the state (i, x), where i is a positive integer between 1 and k, and let h(i, x) denote the unnormalized joint density of their equilibrium distribution. The logarithm of this function is what obj or obj$lud$ calculates. The mixture distribution is the marginal for x derived from the equilibrium distribution h(i, x), that is,

\[ h(x) = \sum_{i=1}^{k} h(i, x) \]

Parallel tempering simulates a product of distributions of a continuous random vector. Denote the state (x_1, ..., x_k), then the unnormalized joint density of the equilibrium distribution is

\[ h(x_1, ..., x_k) = \prod_{i=1}^{k} h(i, x_i) \]

The update mechanism of the Markov chain combines two kinds of elementary updates: jump/swap updates (jump for serial tempering, swap for parallel tempering) and within-component updates. Each iteration of the Markov chain one of these elementary updates is done. With probability 1/2 a jump/swap update is done, and with probability 1/2 a with-component update is done.
Within-component updates are the same for both serial and parallel tempering. They are “random-walk” Metropolis updates with multivariate normal proposal, the proposal distribution being determined by the argument `scale`. In serial tempering, the `x` part of the current state `(i, x)` is updated preserving `h(i, x)`. In parallel tempering, an index `i` is chosen at random and the part of the state `x_i` representing that component is updated, again preserving `h(i, x)`.

Jump updates choose uniformly at random a neighbor of the current component: if `i` indexes the current component, then it chooses uniformly at random a `j` such that `neighbors[i, j] == TRUE`. It then does a Metropolis-Hastings update for changing the current state from `(i, x)` to `(j, x)`.

Swap updates choose a component uniformly at random and a neighbor of that component uniformly at random: first an index `i` is chosen uniformly at random between 1 and `k`, then an index `j` is chosen uniformly at random such that `neighbors[i, j] == TRUE`. It then does a Metropolis-Hastings update for swapping the states of the two components: interchanging `x_i` and `x_j` while preserving `h(x_1, ..., x_k)`.

The initial state must satisfy `lud(initial, ...) > -Inf` for serial tempering or must satisfy `lud(initial[i,], ...) > -Inf` for each `i` for parallel tempering, where `lud` is either `obj` or `obj$lud`. That is, the initial state must have positive probability.

Value

An object of class "mcmc", subclass "tempering", which is a list containing at least the following components:

- `batch`: the batch means of the continuous part of the state. If `outfun` is missing, an `nbatch` by `k` by `p` array. Otherwise, an `nbatch` by `m` matrix, where `m` is the length of the result of `outfun`.
- `ibatch`: (returned for serial tempering only) an `nbatch` by `k` matrix giving batch means for the multivariate Bernoulli random vector that is all zeros except for a 1 in the 1-th place when the current state is `(i, x)`.
- `acceptx`: fraction of Metropolis within-component proposals accepted. A vector of length `k` giving the acceptance rate for each component.
- `accepti`: fraction of Metropolis jump/swap proposals accepted. A `k` by `k` matrix giving the acceptance rate for each allowed jump or swap component. `NA` for elements such that the corresponding elements of `neighbors` is `FALSE`.
- `initial`: value of argument `initial`.
- `final`: final state of Markov chain.
- `initial.seed`: value of `.Random.seed` before the run.
- `final.seed`: value of `.Random.seed` after the run.
- `time`: running time of Markov chain from `system.time()`.
- `lud`: the function used to calculate log unnormalized density, either `obj` or `obj$lud` from a previous run.
- `nbatch`: the argument `nbatch` or `obj$nbatch`.
- `blen`: the argument `blen` or `obj$blen`.
- `nspac`: the argument `nspac` or `obj$nspac`.
- `outfun`: the argument `outfun` or `obj$outfun`.

Description of additional output when `debug = TRUE` can be found in the vignette `debug`, which is shown by `vignette("debug","mcmc")`. 
Warning

If `outfun` is missing, then the log unnormalized density function can be defined without a … argument and that works fine. One can define it starting `ludfun <- function(state)` and that works or `ludfun <- function(state, foo, bar)`, where `foo` and `bar` are supplied as additional arguments to `temper` and that works too.

If `outfun` is a function, then both it and the log unnormalized density function can be defined without … arguments if they have exactly the same arguments list and that works fine. Otherwise it doesn’t work. Define these functions by

```r
ludfun <- function(state, foo)
outfun <- function(state, bar)
```

and you get an error about unused arguments. Instead define these functions by

```r
ludfun <- function(state, foo, ...)
outfun <- function(state, bar, ...)
```

and supply `foo` and `bar` as additional arguments to `temper`, and that works fine.

In short, the log unnormalized density function and `outfun` need to have … in their arguments list to be safe. Sometimes it works when … is left out and sometimes it doesn’t.

Of course, one can avoid this whole issue by always defining the log unnormalized density function and `outfun` to have only one argument `state` and use global variables (objects in the R global environment) to specify any other information these functions need to use. That too follows the R way. But some people consider that bad programming practice.

A third option is to define either or both of these functions using a function factory. This is demonstrated in the vignette for this package named `demo`, which is shown by `vignette("demo","mcmc")`.

Philosophy of MCMC

This function follows the philosophy of MCMC explained the introductory chapter of the *Handbook of Markov Chain Monte Carlo* (Geyer, 2011a) and in the chapter of that book on tempering and related subjects (Geyer, 2011b). See also the section on philosophy of `metrop`.

Tuning

The `scale` argument must be adjusted so that the acceptance rate for within-component proposals (component `acceptx` of the result returned by this function) is not too low or too high to get reasonable performance. The log unnormalized density function must be chosen so that the acceptance rate for jump/swap proposals (component `accepti` of the result returned by this function) is not too low or too high to get reasonable performance. The former is a vector and the latter is a matrix, and all these rates must be adjusted to be reasonable.

The rates in `accepti` are influenced by the number of components of the tempering mixture distribution, by what those components are (how far apart they are in some unspecified metric on probability distributions), and by the chosen normalizing constants for those distributions.

For examples of tuning tempering, see Geyer (2011b) and also the vignette of this package shown by `vignette("bfst","mcmc")`. The help for R function `metrop` also gives advice on tuning its sampler, which is relevant for tuning the `acceptx` rates.
See also Geyer (1991) and Geyer and Thompson (1995) for the general theory of tuning parallel and serial tempering.
