SNewton: safeguarded Newton methods for function minimization

John C. Nash

2018-11-30

Safeguarded Newton algorithms

So-called Newton methods are among the most commonly mentioned in the solution of nonlinear equations or function minimization. However, as discussed in https://en.wikipedia.org/wiki/Newton%27s_method#History, the Newton or Newton-Raphson method as we know it today was not what either of its supposed originators knew.

This vignette discusses the development of simple safeguarded variants of the Newton method for function minimization in R. Note that there are some resources in R for solving nonlinear equations by Newton-like methods in the packages nleqslv and pracma.

The basic approach

If we have a function $f(x)$, with gradient $g(x)$ and second derivative (Hessian) $H(x)$ the first order condition for an extremum (min or max) is

$$g(x) = 0$$

To ensure a minimum, we want

$$H(x) > 0$$

The first order condition leads to a root-finding problem.

It turns out that $x$ need not be a scalar. We can consider it to be a vector of parameters to be determined. This renders $g(x)$ a vector also, and $H(x)$ a matrix. The conditions of optimality then require a zero gradient and positive-definite Hessian.

The Newton approach to such equations is to provide a guess to the root $x_0$ and to then solve the equation

$$H(x_t) \ast s = -g(x_t)$$

for the search vector $s$. We update $x_t$ to $x_t + s$ and repeat until we have a very small gradient $g(x_t)$. If $H(x)$ is positive definite, we have a reasonable approximation to a (local) minimum.
Motivations

A particular interest in Newton-like methods is its theoretical quadratic convergence. See https://en.wikipedia.org/wiki/Newton%27s_method. That is, the method will converge in one step for a quadratic function \( f(x) \), and for "reasonable" functions will converge very rapidly. There are, however, a number of conditions, and practical programs need to include safeguards against mis-steps in the iterations.

The principal issues concern the possibility that \( H(x) \) may not be positive definite, at least in some parts of the domain, and that the curvature may be such that a unit step \( x_t + s \) does not reduce the function \( f \). We therefore get a number of possible variants of the method when different possible safeguards are applied.

Algorithm possibilities

There are many choices we can make in building a practical code to implement the ideas above. In tandem with the two main issues expressed above, we will consider

- the modification of the solution of the main equation
  \[ H(x_t) \ast s = -g(x_t) \]
  so that a reasonable search vector \( s \) is always generated by avoiding Hessian matrices that are not positive definite.
- the selection of a new set of parameters \( x_{new} = x_t + \text{step} \ast s \) so that the function value \( f(x_{new}) \) is less than \( f(x_t) \).

The second choice above could be made slightly more stringent so that the Armijo condition of sufficient-decrease is met. Adding a curvature requirement gives the Wolfe conditions. See https://en.wikipedia.org/wiki/Wolfe_conditions. The Armijo requirement is generally written

\[ f(x_t + \text{step} \ast s) < f(x_t) + c \ast \text{step} \ast g(x_t)^T \ast s \]

where \( c \) is some number less than 1. Typically \( c = 1e - 4 = 0.0001 \). Note that the product of gradient times search vector is negative for any reasonable situation, since we are trying to go “downhill”.

As a result of the ideas in this section, the code \texttt{snewton()} uses a solution of the Newton equations with the Hessian provided (if this is possible, else we stop), along with a backtracking line search. The code \texttt{snewtonm} uses a Marquardt stabilization of the Hessian to create

\[ Haug = H + 1_n \ast \lambda \]

That is, we add \( \lambda \) times the unit matrix to \( H \). Then we try the set of parameters found by adding the solution of the Newton equations with \( Haug \) in place of \( H \) to the current “best” set of parameters. If this new set of parameters has a higher function value than the “best” so far, we increase \( \lambda \) and try again.

As a result of the ideas in this section, the code \texttt{snewton()} uses a solution of the Newton equations with the Hessian provided (if this is possible, else we stop), along with a backtracking line search. The code \texttt{snewtonm} uses a Marquardt stabilization of the Hessian to create

\[ Haug = H + 1_n \ast \lambda \]

That is, we add \( \lambda \) times the unit matrix to \( H \). Then we try the set of parameters found by adding the solution of the Newton equations with \( Haug \) in place of \( H \) to the current “best” set of parameters. If this new set of parameters has a higher function value than the “best” so far, we increase \( \lambda \) and try again.

A choice to compute the search vector

The primary concern in solving for \( s \) is that the Hessian may not be positive definite. This means that we cannot apply fast and stable methods like the Cholesky decomposition to the matrix. At the time of writing, we use the following approach:
We attempt to solve

\[ H(x_t) \ast s = -g(x_t) \]

with \( R \) directly, and rely on internal checks to catch any cases where the solution fails. We then use \texttt{try()} to stop the program in this case.

Choosing the step size

The traditional Newton approach is that the stepsize is taken to be 1. In practice, this can sometimes mean that the function value is not reduced. As an alternative, we can use a simple backtrack search. We start with \texttt{step = 1} (actually the program allows for the element \texttt{defstep} of the \texttt{control} list to be set to a value other than 1). If the Armijo condition is not met, we replace \texttt{step} with \$ r \ast step \$ where \( r \) is less than 1. Here we suggest \texttt{control$stepdec = 0.2}. We repeat until \( x_t \) satisfies the Armijo condition or \( x_t \) is essentially unchanged by the step.

Here “essentially unchanged” is determined by a test using an offset value, that is, the test

\[(x_t + offset) == (x_t + step \ast d + offset)\]

where \( d \) is the search direction. \texttt{control$offset = 100} is used. We could also, and almost equivalently, use the \( R \) identical function.

This approach has been coded into the \texttt{snewton()} function.

Examples

These examples are coded as a test to the interim package \texttt{snewton}, but as at 2018-7-10 are part of the \texttt{optimx} package. We call these below mostly via the \texttt{optimr()} function to allow compact output to be used, but please note that some count information on the number of hessian evaluations and “iterations” (which generally is an algorithm-specific measure) is not then returned.

A simple example

The following example is trivial, in that the Hessian is a constant matrix, and we achieve convergence immediately.

\begin{verbatim}
x0<-c(1,2,3,4)
fnt <- function(x, fscale=10){
    yy <- length(x):1
    val <- sum((yy*x)^2)*fscale
}
grt <- function(x, fscale=10){
    nn <- length(x)
    yy <- nn:1
    # gg <- rep(NA,nn)
    gg <- 2*(yy^2)*x*fscale
    gg
}
hesst <- function(x, fscale=10){

\end{verbatim}
nn <- length(x)
yy <- nn:1
hh <- diag(2*yy^2*fscale)

require(optimx)

## Loading required package: optimx

t1 <- snewton(x0, fnt, grt, hesst, control=list(trace=0), fscale=3.0)

## Termination code is 0 : relative convergence (4)
## ---------------------------------------

From the number of function and gradient evaluations, it appears \texttt{nlminb()} is not using the Hessian information. Note that the \texttt{snewton()} and \texttt{snewtonm()} functions return count information for iterations and hessian evaluations, but these are not part of the standard \texttt{optim()} (and thus \texttt{optimr()}) result objects.

The Rosenbrock function

```r
require(optimx)
#Rosenbrock banana valley function
f <- function(x){
  return(100*(x[2] - x[1]*x[1])^2 + (1-x[1])^2)
}
#gradient
gr <- function(x){
  return(c(-400*x[1]*(x[2] - x[1]*x[1]) - 2*(1-x[1]), 200*(x[2] - x[1]*x[1])))
}
#Hessian
h <- function(x) {
  a11 <- 2 - 400*x[2] + 1200*x[1]*x[1]; a21 <- -400*x[1]
  return(matrix(c(a11, a21, a21, 200), 2, 2))
}
x0 <- c(-1.2, 1)
```
```r
# sink("mbrn1-170408.txt", split=TRUE)

The Wood function

For nlm() the “standard” start takes more than 100 iterations and returns a non-optimal solution.

#Example: Wood function
#
wood.f <- function(x){
  res <- 100*(x[1]^2-x[2])^2+(1-x[1])^2+90*(x[3]^2-x[4])^2+(1-x[3])^2+
10.1*((1-x[2])^2+(1-x[4])^2)+19.8*(1-x[2])*(1-x[4])
  return(res)
}

#gradient:
wood.g <- function(x){
g1 <- -400*x[1]^3-400*x[1]*x[2]+2*x[1]-2
   g2 <- -200*x[1]^2+220.2*x[2]+19.8*x[4]-40
   g3 <- -360*x[3]^3+360*x[3]*x[4]+2*x[3]-2
   g4 <- -180*x[3]^2+200.2*x[4]+19.8*x[2]-40
  return(c(g1,g2,g3,g4))
}
#hessian:

```r
wood.h <- function(x){
  h11 <- 1200*x[1]^2-400*x[2]^2;  h12 <- -400*x[1]; h13 <- h14 <- 0
  h22 <- 220.2; h23 <- 0;  h24 <- 19.8
  h33 <- 1080*x[3]^2-360*x[4]^2;  h34 <- -360*x[3]
  h44 <- 200.2

  H <- matrix(c(h11,h12,h13,h14,h12,h22,h23,h24,
                h13,h23,h33,h34,h14,h24,h34,h44),ncol=4)

  return(H)
}
```

```
wood.fgh <- function(x){
  fval <- wood.f(x)
  gval <- wood.g(x)
  hval <- wood.h(x)
  attr(fval,"gradient") <- gval
  attr(fval,"hessian")<- hval
  fval
}
```

```
x0 <- c(-3,-1,-3,-1) # wood standard start

require(optimx)
# In 100 iterations, not converged

The Hobbs weed infestation problem

This problem is described in @cnm79. It has various nasty properties. Note that one starting point causes failure of the `snewton()` optimizer.

```r
## Optimization test function HOBBS
## refs (put in .doc??)
## Nash and Walker-Smith (1987, 1989) ...
require(optimx)
