Package ‘pcalg’

April 26, 2019

Version 2.6-2

Date 2019-04-08

Title Methods for Graphical Models and Causal Inference

Description Functions for causal structure learning and causal inference using graphical models. The main algorithms for causal structure learning are PC (for observational data without hidden variables), FCI and RFCI (for observational data with hidden variables), and GIES (for a mix of data from observational studies (i.e. observational data) and data from experiments involving interventions (i.e. interventional data) without hidden variables). For causal inference the IDA algorithm, the Generalized Backdoor Criterion (GBC), the Generalized Adjustment Criterion (GAC) and some related functions are implemented. Functions for incorporating background knowledge are provided.

addBkgKnowledge

Description

Add background knowledge $x \rightarrow y$ to an adjacency matrix and complete the orientation rules from Meek (1995).

Usage

addBkgKnowledge(gInput, x = c(), y = c(), verbose = FALSE, checkInput = TRUE)

Arguments

- **gInput**: graphNEL object or adjacency matrix of type amat.cpdag (see amatType)
- **x, y**: node labels of $x$ or $y$ in the adjacency matrix. $x$ and $y$ can be vectors representing several nodes (see details below).
- **verbose**: If TRUE, detailed output is provided.
- **checkInput**: If TRUE, the input adjacency matrix is carefully checked to see if it is a valid graph using function isValidGraph

Details

If the input is a graphNEL object, it will be converted into an adjacency matrix of type amat.cpdag. If $x$ and $y$ are given and if $amat[y, x] \neq 0$, this function adds orientation $x \rightarrow y$ to the adjacency matrix amat and completes the orientation rules from Meek (1995). If $x$ and $y$ are not specified (or empty vectors) this function simply completes the orientation rules from Meek (1995). If $x$ and $y$ are vectors of length $k$, $k>1$, this function tries to add $x[1] \rightarrow y[1]$ to the adjacency matrix amat and complete the orientation rules from Meek (1995) for every $i$ in $1,...,k$ (see Algorithm 1 in Perkovic et. al, 2017).

Value

An adjacency matrix of type amat.cpdag of the maximally oriented pdag with added background knowledge $x \rightarrow y$ or NULL, if the background knowledge is not consistent with any DAG represented by the PDAG with the adjacency matrix amat.
adjustment

Compute adjustment sets for covariate adjustment.

Description

This function is a wrapper for convenience to the function adjustmentSet from package dagitty.

Usage

adjustment(amat, amat.type, x, y, set.type)
Arguments

amat
adjacency matrix of type amat.cpdag or amat.pag.
amat.type
string specifying the type of graph of the adjacency matrix amat. It can be a DAG (type="dag"), a CPDAG (type="cpdag") or a maximally oriented PDAG (type="pdag") from Meek (1995); then the type of adjacency matrix is assumed to be amat.cpdag. It can also be a MAG (type = "mag") or a PAG (type="pag"); then the type of the adjacency matrix is assumed to be amat.pag.

x
(integer) position of variable x in the adjacency matrix.
y
(integer) position of variable y in the adjacency matrix.
set.type
string specifying the type of adjustment set that should be computed. It can be "minimal", "all" and "canonical". See Details explanations.

Details

If set.type is "minimal", then only minimal sufficient adjustment sets are returned. If set.type is "all", all valid adjustment sets are returned. If set.type is "canonical", a single adjustment set is returned that consists of all (possible) ancestors of x and y, minus (possible) descendants of nodes on proper causal paths. This canonical adjustment set is always valid if any valid set exists at all.

Value

If adjustment sets exist, list of length at least one (list elements might be empty vectors, if the empty set is an adjustment set). If no adjustment set exists, an empty list is returned.

Author(s)

Emilija Perkovic and Markus Kalisch (<kalisch@stat.math.ethz.ch>)

gac for testing if a set satisfies the Generalized Adjustment Criterion.

Examples

```r
# Example 4.1 in Perkovic et. al (2015), Example 2 in Perkovic et. al (2017)
mFig1 <- matrix(c(0,1,1,0,0,0, 1,0,1,1,0, 0,0,0,0,1, 0,1,1,0,1, 0,1,0,1,0,1, 0,0,0,0,0, 6,6), type <- "cpdag"
```
ages

```
x <- 3; y <- 6
## plot(as(t(mFig1), "graphNEL"))

## all
adjustment(amat = mFig1, amat.type = type, x = x, y = y, set.type = "all")
## finds adjustment sets: (2,4), (1,2,4), (4,5), (1,4,5), (2,4,5), (1,2,4,5)

## minimal
adjustment(amat = mFig1, amat.type = type, x = x, y = y, set.type = "minimal")
## finds adjustment sets: (2,4), (4,5), i.e., the valid sets with the fewest elements

## canonical
adjustment(amat = mFig1, amat.type = type, x = x, y = y, set.type = "canonical")
## finds adjustment set: (1,2,4,5)
```

---

**Description**

Estimate an APDAG within the Markov equivalence class of a DAG using AGES.

**Usage**

```r
ages(data, lambda_min = 0.5 * log(nrow(data)), labels = NULL,
     fixedGaps = NULL, adaptive = c("none", "vstructures", "triples"),
     maxDegree = integer(0), verbose = FALSE, ...)
```

**Arguments**

- **data**: A \( n \times p \) matrix (or data frame) containing the observational data.
- **lambda_min**: The smallest penalty parameter value used when computing the solution path of GES.
- **labels**: Node labels; if NULL the names of the columns of the data matrix (or the names in the data frame) are used. If these are not specified the sequence 1 to \( p \) is used.
- **fixedGaps**: logical symmetric matrix of dimension \( p \times p \). If entry \([i, j]\) is TRUE, the result is guaranteed to have no edge between nodes \( i \) and \( j \).
- **adaptive**: indicating whether constraints should be adapted to newly detected v-structures or unshielded triples (cf. details).
- **maxDegree**: Parameter used to limit the vertex degree of the estimated graph. Valid arguments:
  1. Vector of length 0 (default): vertex degree is not limited.
  2. Real number \( r, 0 < r < 1 \): degree of vertex \( v \) is limited to \( r \cdot n_v \), where \( n_v \) denotes the number of data points where \( v \) was not intervened.
3. Single integer: uniform bound of vertex degree for all vertices of the graph.
4. Integer vector of length $p$: vector of individual bounds for the vertex degrees.

verbose

If TRUE, detailed output is provided.

... Additional arguments for debugging purposes and fine tuning.

Details

This function tries to add orientations to the essential graph (CPDAG) found by `ges` (ran with `lambda`=`lambda_min`). It does it aggregating several CPDAGs present in the solution path of GES. Conceptually, AGES starts with the essential graph found by GES ran with `lambda` = `lambda_min`. Then, it checks for further (compatible) orientation information in other essential graphs present in the solution path of GES, i.e., in essential graphs outputted by GES for larger penalty parameters. With compatible we mean that the aggregation process is done such that the final APDAG is still within the Markov equivalence graph represented by the essential graph found by GES in the following sense: an APDAG can always be extended to a DAG without creating new v-structures. This DAG lies in the Markov equivalence class represented by the essential graph found by GES. The algorithm is explained in detail in Eigenmann, Nandy, and Maathuis (2017).

The arguments `fixedgaps` and `adaptive` work also with AGES. However, they have not been studied in Eigenmann, Nandy, and Maathuis (2017). Using the argument `fixedgaps`, one can make sure that certain edges will not be present in the resulting essential graph: if the entry $[i, j]$ of the matrix passed to `fixedgaps` is TRUE, there will be no edge between nodes $i$ and $j$. The argument `adaptive` can be used to relax the constraints encoded by `fixedgaps` according to a modification of GES called ARGES (adaptively restricted greedy equivalence search) which has been presented in Nandy, Hauser and Maathuis (2018):

- When `adaptive` = "vstructures" and the algorithm introduces a new v-structure $a \rightarrow b \leftarrow c$ in the forward phase, then the edge $a \rightarrow c$ is removed from the list of fixed gaps, meaning that the insertion of an edge between $a$ and $c$ becomes possible even if it was forbidden by the initial matrix passed to `fixedgaps`.
- When `adaptive` = "triples" and the algorithm introduces a new unshielded triple in the forward phase (i.e., a subgraph of three nodes $a$, $b$ and $c$ where $a$ and $b$ as well as $b$ and $c$ are adjacent, but $a$ and $c$ are not), then the edge $a \rightarrow c$ is removed from the list of fixed gaps.

With one of the adaptive modifications, the successive application of a skeleton estimation method and GES restricted to an estimated skeleton still gives a consistent estimator of the DAG, which is not the case without the adaptive modification.

For a detailed explanation of the GES function as well as its related object like essential graphs, we refer to the `ges` function.

Differences in the arguments with respect to GES: AGES uses `data` to initialize several scores taken as argument by GES. AGES modifies the forward and backward phases of GES performing single steps in either directions. For this reason, `phase`, `iterate`, and `turning` are not available arguments.

Value

`ages` returns a list with the following four components:
An object of class `EssGraph` containing an estimate of the equivalence class of the underlying DAG.

`repr`  
An object of a class derived from `ParDAG` containing a (random) representative of the estimated equivalence class.

`CPDAGsList`  
A list of p*p matrices containing all CPDAGs considered by AGES in the aggregation processes

`lambda`  
A vector containing the penalty parameter used to obtain the list of CPDAGs mentioned above. GES returns the list of CPDAGs when used with this vector of penalty parameters if used with phases = c("forward","backward") and iterate = FALSE.

Examples

```r
## Example 1: ages adds correct orientations: Bar --> V6 and Bar --> V8
set.seed(77)

p <- 8
n <- 5000
## true DAG:
vars <- c("Author", "Bar", "Ctrl", "Goal", paste0("V",5:8))
gGtrue <- randomDAG(p, prob = 0.3, V = vars)
data = rmvDAG(n, gGtrue)

## Estimate the aggregated PDAG with ages
ages.fit <- ages(data = data)

## Estimate the essential graph with ges
## We specify the phases in order to have a fair comparison of the algorithms
```
## Without the phases specified it would be easy to find examples
## where each algorithm outperforms the other
score <- new("GaussLOpenObsScore", data)
ges.fit <- ges(score, phase = c("forward","backward"), iterate = FALSE)

## Plots
par(mfrow=c(1,3))
plot(ges.fit$essgraph, main="Estimated CPDAG with GES")
plot(ages.fit$essgraph, main="Estimated APDAG with AGES")
plot(gGtrue, main="TrueDAG")

## Example 2: ages adds correct orientations: Author --> Goal and Author --> V5
set.seed(50)
p <- 9
n <- 5000
## true DAG:
vars <- c("Author", "Bar", "Ctrl", "Goal", paste0("V",5:9))
gGtrue <- randomDAG(p, prob = 0.5, V = vars)
data = rmvDAG(n, gGtrue)

## Estimate the aggregated PDAG with ages
ages.fit <- ages(data = data)

## Estimate the essential graph with ges
## We specify the phases in order to have a fair comparison of the algorithms
## Without the phases specified it would be easy to find examples
## where each algorithm outperforms the other
score <- new("GaussLOpenObsScore", data)
ges.fit <- ges(score, phase = c("forward","backward"), iterate = FALSE)

## Plots
par(mfrow=c(1,3))
plot(ges.fit$essgraph, main="Estimated CPDAG with GES")
plot(ages.fit$essgraph, main="Estimated APDAG with AGES")
plot(gGtrue, main="TrueDAG")

## Example 3: ges and ages return the same graph
data(gmG)
data <- gmG$x

## Estimate the aggregated PDAG with ages
ages.fit <- ages(data = data)
amatType

## Estimate the essential graph with ges
score <- new("GaussL0penObsScore", data)
ges.fit <- ges(score)

## Plots
par(mfrow=c(1,3))
plot(ges.fit$essgraph, main="Estimated CPDAG with GES")
plot(ages.fit$essgraph, main="Estimated APDAG with AGES")
plot(gmG8$g, main="TrueDAG")

### amatType

#### Types and Display of Adjacency Matrices in Package 'pcalg'

#### Description

Two types of adjacency matrices are used in package **pcalg**: Type amat.cpdag for DAGs and CPDAGs and type amat.pag for MAGs and PAGs. The required type of adjacency matrix is documented in the help files of the respective functions or classes. If in some functions more detailed information on the graph type is needed (i.e. DAG or CPDAG; MAG or PAG) this information will be passed in a separate argument (see e.g. gac and the examples below).

Note that you get (‘extract’) such adjacency matrices as (S3) objects of class "amat" via the usual as(. , "<class>") coercion.

```r
as(from, "amat")
```

#### Arguments

- `from` an R object of class **pcAlgo**, as returned from skeleton() or pc() or an object of class **fcIalgo**, as from fci() (or rfci, fciPlus, and dag2pag), or an object of class "LINGAM" as returned from lingam().

#### Details

Adjacency matrices are integer valued square matrices with zeros on the diagonal. They can have row- and columnnames; however, most functions will work on the (integer) column positions in the adjacency matrix.

**Coding for type amat.cpdag:**

- 0: No edge or tail
- 1: Arrowhead

Note that the edgemark-code refers to the *row* index (as opposed adjacency matrices of type mag or pag). E.g.:
amat[a,b] = 0 and amat[b,a] = 1 implies a --> b.
amat[a,b] = 1 and amat[b,a] = 0 implies a <-- b.
amat[a,b] = 0 and amat[b,a] = 0 implies a
amat[a,b] = 1 and amat[b,a] = 1 implies a --- b.

Coding for type amat.pag:

0: No edge
1: Circle
2: Arrowhead
3: Tail

Note that the edgemark-code refers to the column index (as opposed adjacency matrices of type dag or cpdag). E.g.:

amat[a,b] = 2 and amat[b,a] = 3 implies a --> b.
amat[a,b] = 3 and amat[b,a] = 2 implies a <-- b.
amat[a,b] = 2 and amat[b,a] = 2 implies a <-> b.
amat[a,b] = 1 and amat[b,a] = 3 implies a --o b.
amat[a,b] = 0 and amat[b,a] = 0 implies a b.

See Also

E.g. gac for a function which takes an adjacency matrix as input; fciAlgo for a class which has an adjacency matrix in one slot.
getGraph(x) extracts the graph object from x, whereas as(*, "amat") gets the corresponding adjacency matrix.

Examples

# Function gac() takes an adjacency matrix of
# any kind as input. In addition to that, the
# precise type of graph (DAG/CPDAG/MAG/PAG) needs
# to be passed as a different argument

# Adjacency matrix of type 'amat.cpdag'
m1 <- matrix(c(0,1,0,1,0,0,0,0,0,0,0,1,
0,0,0,0,0,0,0,0,0,0,0,0), nrow=6, ncol=6)

# more detailed information on the graph type needed by gac()
gac(m1, x=1, y=3, z=NULL, type = "dag")

# Adjacency matrix of type 'amat.cpdag'
m2 <- matrix(c(0,1,1,0,0,0,0,0,0,0,0,0,0,
0,1,1,1,1,0,0,0,0,0,0,0,0), nrow=6, ncol=6)

# more detailed information on the graph type needed by gac()
gac(m2, x=3, y=6, z=c(2,4), type = "cpdag")

# Adjacency matrix of type 'amat.pag'
m3 <- matrix(c(0,2,0,0,3,0,3,3,0,2,0,3,0,2,2,0), 4,4)
amatType

```r
## more detailed information on the graph type needed by gac()
mg3 <- gac(m3, x=2, y=4, z=NULL, type = "mag")
p3 <- gac(m3, x=2, y=4, z=NULL, type = "pag")

## Load predefined data
data(gmG)
n <- nrow(gmG$x)
V <- colnames(gmG$x)

## define sufficient statistics
suffStat <- list(C = cor(gmG$x), n = n)
## estimate CPDAG
skel.fit <- skeleton(suffStat, indepTest = gaussCItest,
                      alpha = 0.01, labels = V)
## Extract the "amat" [and show nicely via 'print()' method]:
as(skel.fit, "amat")

## Function fci() returns an adjacency matrix
## of type amat.pag as one slot.
set.seed(42)
p <- 7
## generate and draw random DAG :
myDAG <- randomDAG(p, prob = 0.4)

## find skeleton and PAG using the FCI algorithm
suffStat <- list(C = cov2cor(trueCov(myDAG)), n = 10^9)
res <- fci(suffStat, indepTest=gaussCItest,
            alpha = 0.999, p=p, doPdsep = FALSE)
str(res)
## get the adjacency matrix (rix) and nicely print() it:
as(res, "amat")

## pcalgo object
## Load predefined data
data(gmG)
n <- nrow(gmG$x)
V <- colnames(gmG$x)

## define sufficient statistics
suffStat <- list(C = cor(gmG$x), n = n)
## estimate CPDAG
skel.fit <- skeleton(suffStat, indepTest = gaussCItest,
                      alpha = 0.01, labels = V)
## Extract Adjacency Matrix - and print (via method 'print amat'):
as(skel.fit, "amat")
```
backdoor

Find Set Satisfying the Generalized Backdoor Criterion (GBC)

Description

This function first checks if the total causal effect of one variable \( x \) onto another variable \( y \) is identifiable via the GBC, and if this is the case it explicitly gives a set of variables that satisfies the GBC with respect to \( x \) and \( y \) in the given graph.

Usage

backdoor amat, x, y, type = "pag", max.chordal = 10, verbose=FALSE

Arguments

- amat: adjacency matrix of type amat.cpdag or amat.pag.
- x, y: (integer) position of variable \( X \) and \( Y \), respectively, in the adjacency matrix.
- type: string specifying the type of graph of the adjacency matrix amat. It can be a DAG (type="dag"), a CPDAG (type="cpdag"); then the type of the adjacency matrix is assumed to be amat.cpdag. It can also be a MAG (type="mag"), or a PAG (type="pag"); then the type of the adjacency matrix is assumed to be amat.pag.
- max.chordal: only if type = "mag", is used in pag2magAM to determine paths too large to be checked for chordality.
- verbose: logical; if true, some output is produced during computation.

Details

This function is a generalization of Pearl’s backdoor criterion, see Pearl (1993), defined for directed acyclic graphs (DAGs), for single interventions and single outcome variable to more general types of graphs (CPDAGs, MAGs, and PAGs) that describe Markov equivalence classes of DAGs with and without latent variables but without selection variables. For more details see Maathuis and Colombo (2015).

The motivation to find a set \( W \) that satisfies the GBC with respect to \( x \) and \( y \) in the given graph relies on the result of the generalized backdoor adjustment:

If a set of variables \( W \) satisfies the GBC relative to \( x \) and \( y \) in the given graph, then the causal effect of \( x \) on \( y \) is identifiable and is given by

\[
P(Y|do(X = x)) = \sum_W P(Y|X, W) \cdot P(W).
\]
This result allows to write post-intervention densities (the one written using Pearl’s do-calculus) using only observational densities estimated from the data.

If the input graph is a DAG (type="dag"), this function reduces to Pearl’s backdoor criterion for single interventions and single outcome variable, and the parents of x in the DAG satisfy the backdoor criterion unless y is a parent of x.

If the input graph is a CPDAG C (type="cpdag"), a MAG M (type="mag"), or a PAG P (type="pag") (with both M and P not allowing selection variables), this function first checks if the total causal effect of x on y is identifiable via the GBC (see Maathuis and Colombo, 2015). If the effect is not identifiable in this way, the output is NA. Otherwise, an explicit set W that satisfies the GBC with respect to x and y in the given graph is found.

At this moment this function is not able to work with an RFCI-PAG.

It is important to note that there can be pair of nodes x and y for which there is no set W that satisfies the GBC, but the total causal effect might be identifiable via some other technique.

For the coding of the adjacency matrix see amatType.

Value

Either NA if the total causal effect is not identifiable via the GBC, or a set if the effect is identifiable via the GBC. Note that if the set W is equal to the empty set, the output is NULL.

### beta.special  
**Compute set of intervention effects**

### Description
This function is DEPRECATED! Use `ida` instead.

### Usage
```r
beta.special(dat=NA, x.pos, y.pos, verbose=0, a=0.01, myDAG=NA,
             myplot=FALSE, perfect=FALSE, method="local", collTest=TRUE,
             pcObj=NA, all.dags=NA, u2pd="rand")
```

### Arguments
- `dat`: Data matrix
- `x.pos`, `y.pos`: integer column positions of `x` and `y` in `dat`.
- `verbose`: 0=no comments, 2=detail on estimates
- `a`: Significance level of tests for finding CPDAG
- `myDAG`: Needed if true correlation matrix shall be computed
- `myplot`: Plot estimated graph
- `perfect`: True cor matrix is calculated from myDAG
- `method`: "local" - local (all combinations of parents in regr.); "global" - all DAGs
- `collTest`: True - Exclude orientations of undirected edges that introduce a new collider
- `pcObj`: Fit of PC Algorithm (CPDAG); if this is available, no new fit is done
- `all.dags`: All DAGs in the format of function allDags; if this is available, no new function call allDags is done
- `u2pd`: function for converting a UDAG to a PDAG; "rand": `udag2pdag`; "relaxed": `udag2pdagRelaxed`; "retry": `udag2pdagSpecial`.

### Value
estimates of intervention effects

### Author(s)
Markus Kalisch (<kalisch@stat.math.ethz.ch>)

### See Also
- `pcAlgo`, `dag2cpdag`: `beta.special.pcObj` for a fast version of `beta.special()`, using a precomputed pc-object.
beta.special.pcObj  Compute set of intervention effects in a fast way

Description

This function is DEPRECATED! Use ida or idafast instead.

Usage

beta.special.pcObj(x.pos, y.pos, pcObj, mcov=NA, amat=NA, amatSkel=NA, t.amat=NA)

Arguments

x.pos  Column of x in dat
y.pos  Column of y in dat
pcObj  Precomputed pc-object
mcov  Covariance that was used in the pc-object fit
amat, amatSkel, t.amat  Matrices that can be precomputed, if needed (see code for details on how to precompute)

Value

estimates of intervention effects

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

binCItest  G square Test for (Conditional) Independence of Binary Variables

Description

$G^2$ test for (conditional) independence of binary variables $X$ and $Y$ given the (possibly empty) set of binary variables $S$.

binCItest() is a wrapper of gSquareBin(), to be easily used in skeleton, pc and fci.
Usage

`gSquareBin(x, y, S, dm, adaptDF = FALSE, n.min = 10*df, verbose = FALSE)`

`binCITest(x, y, S, suffStat)`

Arguments

- `x, y` (integer) position of variable X and Y, respectively, in the adjacency matrix.
- `S` (integer) positions of zero or more conditioning variables in the adjacency matrix.
- `dm` data matrix (with \{0, 1\} entries).
- `adaptDF` logical specifying if the degrees of freedom should be lowered by one for each zero count. The value for the degrees of freedom cannot go below 1.
- `n.min` the smallest \(n\) (number of observations, `nrow(dm)`) for which the \(G^2\) test is computed; for smaller \(n\), independence is assumed \((G^2 := 1)\) with a warning. The default is \(10m\), where \(m\) is the degrees of freedom assuming no structural zeros, \(2^{|S|}\).
- `verbose` logical or integer indicating that increased diagnostic output is to be provided.
- `suffStat` a list with two elements, "dm", and "adaptDF" corresponding to the above two arguments of `gSquareBin()`.

Details

The \(G^2\) statistic is used to test for (conditional) independence of X and Y given a set S (can be NULL). This function is a specialized version of `gSquareDis` which is for discrete variables with more than two levels.

Value

The p-value of the test.

Author(s)

Nicoletta Andri and Markus Kalisch (<kalisch@stat.math.ethz.ch>)

References

See Also

- `gSquareDis` for a (conditional) independence test for discrete variables with more than two levels.
- `dsepTest`, `gaussCITest` and `disCITest` for similar functions for a d-separation oracle, a conditional independence test for Gaussian variables and a conditional independence test for discrete variables, respectively.
- `skeleton`, `pc` or `fci` which need a testing function such as `binCITest`. 
Examples

n <- 100
set.seed(123)

## Simulate *independent data of (0,1)-variables:
x <- rbinom(n, 1, pr=1/2)
y <- rbinom(n, 1, pr=1/2)
z <- rbinom(n, 1, pr=1/2)
dat <- cbind(x,y,z)

binCITest(1,3,2, list(dm = dat, adaptDF = FALSE)) # 0.36, not signif.
binCITest(1,3,2, list(dm = dat, adaptDF = TRUE )) # the same, here

## Simulate data from a chain of 3 variables: x1 -> x2 -> x3
set.seed(12)
b0 <- 0
b1 <- 1
b2 <- 1
n <- 10000
x1 <- rbinom(n, size=1, prob=1/2) # sample(c(0,1), n, replace=TRUE)

## NB: plogis(u) := "expit(u)" := exp(u) / (1 + exp(u))
p2 <- plogis(b0 + b1*x1) ; x2 <- rbinom(n, 1, prob = p2) # (0,1)
p3 <- plogis(b0 + b2*x2) ; x3 <- rbinom(n, 1, prob = p2) # (0,1)

ftable(xtabs(~ x1*x2+x3))
dat <- cbind(x1,x2,x3)

## Test marginal and conditional independencies
gSquareBin(3,1,NULL,dat, verbose=TRUE)
gSquareBin(3,1, 2, dat)
gSquareBin(1,3, 2, dat) # the same
gSquareBin(1,3, 2, dat, adaptDF=TRUE, verbose = 2)

checkTriple

Check Consistency of Conditional Independence for a Triple of Nodes

Description

For each subset of nbrsA and nbrsC where a and c are conditionally independent, it is checked if b is in the conditioning set.

Usage

checkTriple(a, b, c, nbrsA, nbrsC,
    sepsetA, sepsetC,
    suffStat, indepTest, alpha, version.unf = c(NA, NA),
    maj.rule = FALSE, verbose = FALSE)
Arguments

- `a`, `b`, `c` (integer) positions in adjacency matrix for nodes `a`, `b`, and `c`, respectively.
- `nbrsA`, `nbrsC` (integer) position in adjacency matrix for neighbors of `a` and `c`, respectively.
- `sepsetA` vector containing `Sepset(a, c)`.
- `sepsetC` vector containing `Sepset(c, a)`.
- `suffStat` a list of sufficient statistics for independent tests; see, e.g., `pc`.
- `indepTest` a function for the independence test, see, e.g., `pc`.
- `alpha` significance level of test.
- `version.unf` (integer) vector of length two:
    2 - it also checks if there at all exists any sepset which is a subset of the neighbors (there might be none, although `b` is in the sepset, which indicates an ambiguous situation);
  - `version.unf[2]`: 1 - do not consider the initial sepsets `sepsetA` and `sepsetC` (same as Tetrad),
    2 - consider if `b` is in `sepsetA` or `sepsetC`.
- `maj.rule` logical indicating that the following majority rule is applied: if `b` is in less than 50% of the checked sepsets, we say that `b` is in no sepset. If `b` is in more than 50% of the checked sepsets, we say that `b` is in all sepsets. If `b` is in exactly 50% of the checked sepsets, the triple is considered 'ambiguous'.
- `verbose` Logical asking for detailed output of intermediate steps.

Details

This function is used in the conservative versions of structure learning algorithms.

Value

- `decision` Decision on possibly ambiguous triple, an integer code,
  - 1 `b` is in NO sepset (make v-structure);
  - 2 `b` is in ALL sepsets (make no v-structure);
  - 3 `b` is in SOME but not all sepsets (ambiguous triple)
- `vers` Version (1 or 2) of the ambiguous triple (1=normal ambiguous triple that is `b` is in some sepsets; 2=triple coming from `version.unf[1]==2`, that is, `a` and `c` are indep given the initial sepset but there doesn't exist a subset of the neighbours that d-separates them.)
- `sepsetA` Updated version of `sepsetA`
- `sepsetC` Updated version of `sepsetC`

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Diego Colombo.

#$ SepsetC : int 1

checkTriple(a, b, c,
nbrsA = c(1,5,7),
nbrsC = c(1,5),
Description

Compares the true undirected graph with an estimated undirected graph in terms of True Positive Rate (TPR), False Positive Rate (FPR) and True Discovery Rate (TDR).

Usage

```r
compareGraphs(gl, gt)
```

Arguments

- `gl`: Estimated graph (graph object)
- `gt`: True graph (graph object)

Details

If the input graph is directed, the directions are omitted. Special cases:

- If the true graph contains no edges, the tpr is defined to be zero.
- Similarly, if the true graph contains no gaps, the fpr is defined to be one.
- If there are no edges in the true graph and there are none in the estimated graph, tdr is one. If there are none in the true graph but there are some in the estimated graph, tdr is zero.

Value

A named numeric vector with three numbers:

- `tpr`: True Positive Rate: Number of correctly found edges (in estimated graph) divided by number of true edges (in true graph)
- `fpr`: False Positive Rate: Number of incorrectly found edges divided by number of true gaps (in true graph)
- `tdr`: True Discovery Rate: Number of correctly found edges divided by number of found edges (both in estimated graph)

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler
Test Conditional Independence of Gaussians via Fisher’s Z

Using Fisher’s z-transformation of the partial correlation, test for zero partial correlation of sets of normally / Gaussian distributed random variables.

The gaussCItest() function, using zStat() to test for (conditional) independence between gaussian random variables, with an interface that can easily be used in skeleton, pc and fci.

Usage

condIndFisherZ(x, y, S, C, n, cutoff, verbose = )
zStat (x, y, S, C, n)
gaussCItest (x, y, S, suffStat)
condIndFisherZ

Arguments

\(x, y, S\) (integer) position of variable \(X\), \(Y\) and set of variables \(S\), respectively, in the adjacency matrix. It is tested, whether \(X\) and \(Y\) are conditionally independent given the subset \(S\) of the remaining nodes.

\(C\) Correlation matrix of nodes

\(n\) Integer specifying the number of observations ("samples") used to estimate the correlation matrix \(C\).

cutoff Numeric cutoff for significance level of individual partial correlation tests. Must be set to \(\text{qnorm}(1 - \alpha/2)\) for a test significance level of \(\alpha\).

verbose Logical indicating whether some intermediate output should be shown; currently not used.

suffStat A list with two elements, "C" and "n", corresponding to the above arguments with the same name.

Details

For gaussian random variables and after performing Fisher’s z-transformation of the partial correlation, the test statistic \(z\text{Stat}()\) is (asymptotically for large enough \(n\)) standard normally distributed.

Partial correlation is tested in a two-sided hypothesis test, i.e., basically, \(\text{condIndFisherZ}(\cdot) = \text{abs}(z\text{Stat}(\cdot)) > \text{qnorm}(1 - \alpha/2)\).

In a multivariate normal distribution, zero partial correlation is equivalent to conditional independence.

Value

\(z\text{Stat}()\) gives a number

\[ Z = \sqrt{n - |S| - 3 \cdot \log((1 + r)/(1 - r))}/2 \]

which is asymptotically normally distributed under the null hypothesis of correlation 0.

\(\text{condIndFisherZ}()\) returns a logical \(L\) indicating whether the "partial correlation of \(x\) and \(y\) given \(S\) is zero" could not be rejected on the given significance level. More intuitively and for multivariate normal data, this means: If \(TRUE\) then it seems plausible, that \(x\) and \(y\) are conditionally independent given \(S\). If \(FALSE\) then there was strong evidence found against this conditional independence statement.

gaussCItest() returns the p-value of the test.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler

References

*pcorOrder* for computing a partial correlation given the correlation matrix in a recursive way.

*dsepTest*, *disCItest* and *binCItest* for similar functions for a d-separation oracle, a conditional independence test for discrete variables and a conditional independence test for binary variables, respectively.

Examples

```r
set.seed(42)
## Generate four independent normal random variables
n <- 20
data <- matrix(rnorm(n*4), n, 4)
## Compute corresponding correlation matrix
corMatrix <- cor(data)
## Test, whether variable 1 (col 1) and variable 2 (col 2) are
## independent given variable 3 (col 3) and variable 4 (col 4) on 0.05
## significance level
x <- 1
y <- 2
S <- c(3, 4)
n <- 20
alpha <- 0.05
cutoff <- qnorm(1-alpha/2)
(b1 <- condIndFisherZ(x, y, S, corMatrix, n, cutoff))
  # -> 1 and 2 seem to be conditionally independent given 3,4

## Now an example with conditional dependence
data <- matrix(rnorm(n*3), n, 3)
data[,3] <- 2*x[data[,1]]
corMatrix <- cor(data)
(b2 <- condIndFisherZ(1, 3, 2, corMatrix, n, cutoff))
  # -> 1 and 3 seem to be conditionally dependent given 2

## simulate another dep.case: x -> y -> z
set.seed(29)
x <- rnorm(100)
y <- 3*x + rnorm(100)
z <- 2*y + rnorm(100)
dat <- cbind(x, y, z)

## analyze data
suffStat <- list(C = cor(dat), n = nrow(dat))
gaussCItest(1, 3, NULL, suffStat) ## dependent [highly signif.]
gaussCItest(1, 3, 2, suffStat) ## independent | S
```

---

**corGraph**

*Computing the correlation graph*
Description

Computes the correlation graph. This is the graph in which an edge is drawn between node i and node j, if the null hypothesis “Correlation between Xᵢ and Xⱼ is zero” can be rejected at the given significance level α(α).

Usage

```r
corGraph(dm, alpha=0.05, Cmethod="pearson")
```

Arguments

dm numeric matrix with rows as samples and columns as variables.
alpha significance level for correlation test (numeric)
Cmethod a character string indicating which correlation coefficient is to be used for the test. One of "pearson", "kendall", or "spearman", can be abbreviated.

Value

Undirected correlation graph, a graph object (package graph); `getGraph` for the “fitted” graph.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler

Examples

```r
## create correlated samples
x1 <- rnorm(100)
x2 <- rnorm(100)
mat <- cbind(x1, x2, x3 = x1+x2)

if (require(Rgraphviz)) {
  # 'analyze the data'
  (g <- corGraph(mat)) # a 'graphNEL' graph, undirected
  plot(g) # ==> (1) and (2) are each linked to (3)

  # use different significance level and different method
  (g2 <- corGraph(mat, alpha=0.01, Cmethod="kendall"))
  plot(g2) # same edges as 'g'
}
```
Description

Convert a DAG (Directed Acyclic Graph) to a Completed Partially Directed Acyclic Graph (CPDAG).

Usage

dag2cpdag(g)

Arguments

- g: an R object of class "graph" (package graph), representing a DAG.

Details

This function converts a DAG into its corresponding (unique) CPDAG as follows. Because every DAG in the Markov equivalence class described by a CPDAG shares the same skeleton and the same v-structures, this function takes the skeleton and the v-structures of the given DAG g. Afterwards it simply uses the 3 orientation rules of the PC algorithm (see references) to orient as many of the remaining undirected edges as possible.

The function is a simple wrapper function for dag2essgraph which is more powerful since it also allows the calculation of the Markov equivalence class in the presence of interventional data.

The output of this function is exactly the same as the one using

pc(suffStat, indepTest, alpha, labels)

using the true correlation matrix in the function gaussCItest with a large virtual sample size and a large alpha, but it is much faster.

Value

A graph object containing the CPDAG.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Alain Hauser(<alain.hauser@bfh.ch>)

References

dag2essgraph

Convert a DAG to an Essential Graph

Description

Convert a DAG to an (interventional or observational) essential graph.

Usage

dag2essgraph(dag, targets = list(integer(0)))

Arguments

dag

The DAG whose essential graph has to be calculated. Different representations are possible: dag can be an adjacency matrix, an object of graphNEL (package graph), or an instance of a class derived from ParDAG.

targets

List of intervention targets with respect to which the essential graph has to be calculated. An observational setting is represented by one single empty target (list(integer(0))).
Details

This function converts a DAG to its corresponding (interventional or observational) essential graph, using the algorithm of Hauser and Bühlmann (2012).

The essential graph is a partially directed graph that represents the (interventional or observational) Markov equivalence class of a DAG. It has the same skeleton as the DAG; a directed edge represents an arrow that has a common orientation in all representatives of the (interventional or observational) Markov equivalence class, whereas an undirected edge represents an arrow that has different orientations in different representatives of the equivalence class. In the observational case, the essential graph is also known as “CPDAG” (Spirtes et al., 2000).

In a purely observational setting (i.e., if targets = list(integer(0))), the function yields the same graph as dag2cpdag.

Value

Depending on the class of dag, the essential graph is returned as

- an adjacency matrix, if dag is an adjacency matrix
- an instance of graphNEL, if dag is an instance of graphNEL,
- an instance of EssGraph, if dag is an instance of a class derived from ParDAG.

Author(s)

Alain Hauser (<alain.hauser@bfh.ch>)

### `dag2pag` *Convert a DAG with latent variables into a PAG*

**Description**

Convert a DAG with latent variables into its corresponding (unique) Partial Ancestral Graph (PAG).

**Usage**

```
dag2pag(suffStat, indepTest, graph, L, alpha, rules = rep(TRUE,10),
         verbose = FALSE)
```

**Arguments**

- `suffStat`: the sufficient statistics, a list containing all necessary elements for the conditional independence decisions in the function `indepTest`.  
- `indepTest`: a function for testing conditional independence. The function is internally called as `indepTest(x,y,S,suffStat)`, and tests conditional independence of `x` and `y` given `S`. Here, `x` and `y` are variables, and `S` is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). `suffStat` is a list containing all relevant elements for the conditional independence decisions. The return value of `indepTest()` is the p-value of the test for conditional independence.  
- `graph`: a DAG with p nodes, a graph object. The graph must be topological sorted (for example produced using `randomDAG`).  
- `L`: array containing the labels of the nodes in the graph corresponding to the latent variables.  
- `alpha`: significance level in (0,1) for the individual conditional independence tests.  
- `rules`: logical vector of length 10 indicating which rules should be used when directing edges. The order of the rules is taken from Zhang (2009).  
- `verbose`: logical; if TRUE, detailed output is provided.
Details
This function converts a DAG (graph object) with latent variables into its corresponding (unique) PAG, an \texttt{fcialgo} class object, using the ancestor information and conditional independence tests entailed in the true DAG. The output of this function is exactly the same as the one using

\[
\text{fc}\text{i}(\text{suffStat}, \text{gaussCItest}, p, \text{alpha}, \text{rules} = \text{rep}(\text{TRUE}, 10))
\]

using the true correlation matrix in \texttt{gaussCItest()} with a large “virtual sample size” and a large alpha, but it is much faster, see the example.

Value
An object of \texttt{class fcialgo}, containing the estimated graph (in the form of an adjacency matrix with various possible edge marks), the conditioning sets that lead to edge removals (sepset) and several other parameters.

Author(s)
Diego Colombo and Markus Kalisch <kalisch@stat.math.ethz.ch>.

References

See Also
\texttt{fci}, \texttt{pc}

Examples

```r
## create the graph
set.seed(78)
g <- randomDAG(10, prob = 0.25)
graph::nodes(g) # "1" "2" ... "10" % FIXME: should be kept in result!

## define nodes 2 and 6 to be latent variables
L <- c(2,6)

## compute the true covariance matrix of g
cov.mat <- trueCov(g)
## transform covariance matrix into a correlation matrix
true.corr <- cov2cor(cov.mat)

## Find PAG
## as dependence "oracle", we use the true correlation matrix in
## gaussCItest() with a large "virtual sample size" and a large alpha:
system.time(
  true.pag <- dag2pag(suffStat = list(C = true.corr, n = 10^9),
                      indepTest = gaussCItest,
                      graph=g, L=L, alpha = 0.9999))
```
# disCItest

**G square Test for (Conditional) Independence of Discrete Variables**

### Description

\( G^2 \) test for (conditional) independence of *discrete* (each with a *finite* number of “levels”) variables \( X \) and \( Y \) given the (possibly empty) set of discrete variables \( S \).

\( \text{disCItest}() \) is a wrapper of \( \text{gSquareDis}() \), to be easily used in \( \text{skeleton, pc} \) and \( \text{fci} \).

### Usage

```r
\( \text{disCItest}(x, y, S, \text{dm}, nlev, \text{adaptDF} = \text{FALSE}, \text{n.min} = 10^\text{df}, \text{verbose} = \text{FALSE}) \)
```

### Arguments

- **x, y**: (integer) position of variable \( X \) and \( Y \), respectively, in the adjacency matrix.
- **S**: (integer) positions of zero or more conditioning variables in the adjacency matrix.
- **dm**: data matrix (rows: samples, columns: variables) with integer entries; the k levels for a given column must be coded by the integers 0,1,...,k-1. (see example)
- **nlev**: optional vector with numbers of levels for each variable in \( \text{dm} \).
- **adaptDF**: logical specifying if the degrees of freedom should be lowered by one for each zero count. The value for the degrees of freedom cannot go below 1.
- **n.min**: the smallest \( n \) (number of observations, \( \text{nrow}(\text{dm}) \)) for which the \( G^2 \) test is computed; for smaller \( n \), independence is assumed \( (G^2 := 1) \) with a warning. The default is \( 10m \), where \( m \) is the degrees of freedom assuming no structural zeros, here, the product of all the number of levels \( (\text{nlev}[x]-1) * (\text{nlev}[y]-1) * \text{prod}(\text{nlev}[S]) \).
verbose logical or integer indicating that increased diagnostic output is to be provided.
suffStat a list with three elements, "dm", "nlev", "adaptDF": each corresponding to the above arguments of gSquareDis().

Details
The $G^2$ statistic is used to test for (conditional) independence of X and Y given a set S (can be NULL). If only binary variables are involved, gSquareBin is a specialized (a bit more efficient) alternative to gSquareDis().

Value
The p-value of the test.

Author(s)
Nicoletta Andri and Markus Kalisch (<kalisch@stat.math.ethz.ch>).

References

See Also
gSquareBin for a (conditional) independence test for binary variables.

suffStat <- list(dm = dat, nlev = c(3,4,2), adaptDF = FALSE)
disCitest(1,3,2,suffStat)
dreach: Compute D-SEP(x,y,G)

Description

Let x and y be two distinct vertices in a mixed graph G. This function computes D-SEP(x,y,G), which is defined as follows:

A node v is in D-SEP(x,y,G) iff v is not equal to x and there is a collider path between x and v in G such that every vertex on this path is an ancestor of x or y in G.

Usage

dreach(x, y, amat, verbose = FALSE)

Arguments

x First argument of D-SEP, given as the column number of the node in the adjacency matrix.
y Second argument of D-SEP, given as the column number of the node in the adjacency matrix (y must be different from x).
amat Adjacency matrix of type amat.pag.
verbose Logical specifying details should be on output

Value

Vector of column positions indicating the nodes in D-SEP(x,y,G).

dsep

Test for d-separation in a DAG

Description

This function tests for d-separation of nodes in a DAG.

Usage

dsep(a, b, S=NULL, g, john.pairs = NULL)

Arguments

a  Label (sic!) of node A
b  Label (sic!) of node B
S  Labels (sic!) of set of nodes on which it is conditioned, maybe empty
g  The Directed Acyclic Graph (object of class "graph", see graph-class from the package graph)
john.pairs  The shortest path distance matrix for all pairs of nodes as computed (also by default) in johnson.all.pairs.sp from package RBGL.

Details

This function checks separation in the moralized graph as explained in Lauritzen (2004).

Value

TRUE if a and b are d-separated by S in G, otherwise FALSE.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

dsepTest

Test for d-separation in a DAG

Description

Tests for d-separation of nodes in a DAG. dsepTest() is written to be easily used in skeleton, pc, fci.

Usage

dsepTest(x, y, S=NULL, suffStat)

Arguments

- **x, y** (integer) position of variable X and Y, respectively, in the adjacency matrix.
- **S** (integer) positions of zero or more conditioning variables in the adjacency matrix.
- **suffStat** a list with two elements,
  - "g" Containing the Directed Acyclic Graph (object of class "graph", see graph-class from the package graph), and
  - "jp" Containing the shortest path distance matrix for all pairs of nodes as computed by johnson.all.pairs.sp from package RBGL.

Details

The function is based on dsep. For details on d-separation see the reference Lauritzen (2004).
**Value**

If x and y are d-separated by S in DAG G the result is 1, otherwise it is 0. This is analogous to the p-value of an ideal (without sampling error) conditional independence test on any distribution that is faithful to the DAG G.

if (require(Rgraphviz)) {
  ## plot the DAG
  plot(myDAG, main = "randomDAG(10, prob = 0.2")
}

## define sufficient statistics (d-separation oracle)
suffStat <- list(g = myDAG, jp = RBGL::johnson.all.pairs.sp(myDAG))

dsepTest(1,6, S = NULL, suffStat) ## not d-separated
dsepTest(1,6, S = 3, suffStat) ## not d-separated by node 3
dsepTest(1,6, S = c(3,4), suffStat) ## d-separated by node 3 and 4
```

---

**Description**

This class represents an (observational or interventional) essential graph.
Details

An observational or interventional Markov equivalence class of DAGs can be uniquely represented
by a partially directed graph, the essential graph. Its edges have the following interpretation:

1. a directed edge $a \rightarrow b$ stands for an arrow that has the same orientation in all representatives
   of the Markov equivalence class;
2. an undirected edge $a - b$ stands for an arrow that is oriented in one way in some representatives
   of the equivalence class and in the other way in other representatives of the equivalence class.

Extends

All reference classes extend and inherit methods from "envRefClass".

Constructor

`new("EssGraph", nodes, in.edges, ...)

nodes Vector of node names; cf. also field .nodes.

in.edges A list of length $p$ consisting of index vectors indicating the edges pointing into the nodes
of the DAG.

Fields

.nodes: Vector of node names; defaults to as.character(1:p), where $p$ denotes the number of
nodes (variables) of the model.

.in.edges: A list of length $p$ consisting of index vectors indicating the edges pointing into the
nodes of the DAG.

targets List of mutually exclusive intervention targets with respect to which Markov equivalence
is defined.

score: Object of class `Score`; used internally for score-based causal inference.

Class-Based Methods

Most class-based methods are only for internal use. Methods of interest for the user are:

`repr()`: Yields a representative causal model of the equivalence class, an object of a class derived
from `Score`. Since the representative is not only characterized by the DAG, but also by ap-
propriate parameters, the field `score` must be assigned for this method to work. The DAG is
drawn at random; note that all representatives are statistically indistinguishable under a given
set of intervention targets.

`node.count()`: Yields the number of nodes of the essential graph.

`edge.count()`: Yields the number of edges of the essential graph. Note that `unoriented` edges
count as 2, whereas `oriented` edges count as 1 due to the internal representation.

Methods

`plot` signature(x = "EssGraph", y = "ANY"): plots the essential graph. In the plot, undirected
and bidirected edges are equivalent.

Examples

showClass("EssGraph")

description

Estimate a Partial Ancestral Graph (PAG) from observational data, using the FCI (Fast Causal Inference) algorithm.

Usage

fci(suffStat, indepTest, alpha, labels, p,
  skel.method = c("stable", "original", "stable.fast"),
  type = c("normal", "anytime", "adaptive"),
  fixedGaps = NULL, fixedEdges = NULL,
  NADelete = TRUE, m.max = Inf, pdsep.max = Inf,
  rules = rep(TRUE, 10), dopdsep = TRUE, biCC = FALSE,
  conservative = FALSE, maj.rule = FALSE,
  numCores = 1, verbose = FALSE)

Arguments

suffStat sufficient statistics: A named list containing all necessary elements for the conditional independence decisions in the function indepTest.

indepTest a function for testing conditional independence. The function is internally called as indepTest(x, y, S, suffStat), and tests conditional independence of x and y given S. Here, x and y are variables, and S is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). suffStat is a list with all relevant information, see above. The return value of indepTest() is the p-value of the test for conditional independence.

alpha numeric significance level (in (0, 1)) for the individual conditional independence tests.

labels (optional) character vector of variable (or “node”) names. Typically preferred to specifying p.

p (optional) number of variables (or nodes). May be specified if labels are not, in which case labels is set to 1:p.
skel.method  character string specifying method; the default, "stable" provides an order-independent skeleton, see skeleton.

type  character string specifying the version of the FCI algorithm to be used. By default, it is "normal", and so the normal FCI algorithm is called. If set to "anytime", the 'Anytime FCI' is called and m.max needs to be specified. If set to "adaptive", the 'Adaptive Anytime FCI' is called and m.max is not used. For more information, see Details.

fixedGaps  logical matrix of dimension p*p. If entry [i,j] or [j,i] (or both) are TRUE, the edge i-j is removed before starting the algorithm. Therefore, this edge is guaranteed to be absent in the resulting graph.

fixedEdges  logical matrix of dimension p*p. If entry [i,j] or [j,i] (or both) are TRUE, the edge i-j is never considered for removal. Therefore, this edge is guaranteed to be present in the resulting graph.

NAdelete  If indepTest returns NA and this option is TRUE, the corresponding edge is deleted. If this option is FALSE, the edge is not deleted.

m.max  Maximum size of the conditioning sets that are considered in the conditional independence tests.

pdsep.max  Maximum size of Possible-D-SEP for which subsets are considered as conditioning sets in the conditional independence tests. If the nodes x and y are adjacent in the graph and the size of Possible-D-SEP(x) \( \backslash x \backslash y \) is bigger than pdsep.max, the edge is simply left in the graph. Note that if pdsep.max is less than Inf, the final PAG may be a supergraph of the one computed with pdsep.max = Inf, because fewer tests may have been performed in the former.

rules  Logical vector of length 10 indicating which rules should be used when directing edges. The order of the rules is taken from Zhang (2008).

doPdsep  If TRUE, Possible-D-SEP is computed for all nodes, and all subsets of Possible-D-SEP are considered as conditioning sets in the conditional independence tests, if not defined otherwise in pdsep.max. If FALSE, Possible-D-SEP is not computed, so that the algorithm simplifies to the Modified PC algorithm of Spirtes, Glymour and Scheines (2000, p.84).

biCC  If TRUE, only nodes on paths between nodes x and y are considered to be in Possible-D-SEP(x) when testing independence between x and y. Uses biconnected components, biConnComp from RBGL.

conservative  Logical indicating if the unshielded triples should be checked for ambiguity the second time when v-structures are determined. For more information, see details.

maj.rule  Logical indicating if the unshielded triples should be checked for ambiguity the second time when v-structures are determined using a majority rule idea, which is less strict than the standard conservative. For more information, see details.

numCores  Specifies the number of cores to be used for parallel estimation of skeleton.

verbose  If true, more detailed output is provided.

Details

This function is a generalization of the PC algorithm (see pc), in the sense that it allows arbitrarily many latent and selection variables. Under the assumption that the data are faithful to a DAG
that includes all latent and selection variables, the FCI algorithm (Fast Causal Inference algorithm) (Spirtes, Glymour and Scheines, 2000) estimates the Markov equivalence class of MAGs that describe the conditional independence relationships between the observed variables.

We estimate an equivalence class of maximal ancestral graphs (MAGs) instead of DAGs, since DAGs are not closed under marginalization and conditioning (Richardson and Spirtes, 2002).

An equivalence class of a MAG can be uniquely represented by a partial ancestral graph (PAG). A PAG contains the following types of edges: o-o, o-, o->, ->, <->, -. The bidirected edges come from hidden variables, and the undirected edges come from selection variables. The edges have the following interpretation: (i) there is an edge between x and y if and only if variables x and y are conditionally dependent given S for all sets S consisting of all selection variables and a subset of the observed variables; (ii) a tail on an edge means that this tail is present in all MAGs in the Markov equivalence class; (iii) an arrowhead on an edge means that this arrowhead is present in all MAGs in the Markov equivalence class; (iv) a o-edgemark means that there is at least one MAG in the Markov equivalence class where the edgemark is a tail, and at least one where the edgemark is an arrowhead. Information on the interpretation of edges in a MAG can be found in the references given below.

The first part of the FCI algorithm is analogous to the PC algorithm. It starts with a complete undirected graph and estimates an initial skeleton using skeletonH*L method which produces an initial order-independent skeleton, see skeleton for more details. All edges of this skeleton are of the form o-o. Due to the presence of hidden variables, it is no longer sufficient to consider only subsets of the neighborhoods of nodes x and y to decide whether the edge x oMo y should be removed. Therefore, the initial skeleton may contain some superfluous edges. These edges are removed in the next step of the algorithm which requires some orientations. Therefore, the v-structures are determined using the conservative method (see discussion on conservative below).

After the v-structures have been oriented, Possible-D-SEP sets for each node in the graph are computed at once. To decide whether edge x oMo y should be removed, one performs conditional independence tests of x and y given all possible subsets of Possible-D-SEP(x) and of Possible-D-SEP(y). The edge is removed if a conditional independence is found. This produces a fully order-independent final skeleton as explained in Colombo and Maathuis (2014). Subsequently, the v-structures are newly determined on the final skeleton (using information in sepset). Finally, as many as possible undetermined edge marks (o) are determined using (a subset of) the 10 orientation rules given by Zhang (2008).

The “Anytime FCI” algorithm was introduced by Spirtes (2001). It can be viewed as a modification of the FCI algorithm that only performs conditional independence tests up to and including order m.max when finding the initial skeleton, using the function skeleton, and the final skeleton, using the function pdsep. Thus, Anytime FCI performs fewer conditional independence tests than FCI. To use the Anytime algorithm, one sets type = "anytime" and needs to specify m.max, the maximum size of the conditioning sets.

The “Adaptive Anytime FCI” algorithm was introduced by Colombo et. al (2012). The first part of the algorithm is identical to the normal FCI described above. But in the second part when the final skeleton is estimated using the function pdsep, the Adaptive Anytime FCI algorithm only performs conditional independence tests up to and including order m.max, where m.max is the maximum size of the conditioning sets that were considered to determine the initial skeleton using the function skeleton. Thus, m.max is chosen adaptively and does not have to be specified by the user.

Conservative versions of FCI, Anytime FCI, and Adaptive Anytime FCI are computed if conservative = TRUE is specified. After the final skeleton is computed, all potential v-structures a-b-c are checked in the
following way. We test whether \(a\) and \(c\) are independent conditioning on any subset of the neighbors of \(a\) or any subset of the neighbors of \(c\). When a subset makes \(a\) and \(c\) conditionally independent, we call it a separating set. If \(b\) is in no such separating set or in all such separating sets, no further action is taken and the normal version of the FCI, Anytime FCI, or Adaptive Anytime FCI algorithm is continued. If, however, \(b\) is in only some separating sets, the triple \(a-b-c\) is marked ‘ambiguous’. If \(a\) is independent of \(c\) given some \(S\) in the skeleton (i.e., the edge \(a\-c\) dropped out), but \(a\) and \(c\) remain dependent given all subsets of neighbors of either \(a\) or \(c\), we will call all triples \(a-b-c\) ‘unambiguous’. This is because in the FCI algorithm, the true separating set might be outside the neighborhood of either \(a\) or \(c\). An ambiguous triple is not oriented as a v-structure. Furthermore, no further orientation rule that needs to know whether \(a-b-c\) is a v-structure or not is applied. Instead of using the conservative version, which is quite strict towards the v-structures, Colombo and Maathuis (2014) introduced a less strict version for the v-structures called majority rule. This adaptation can be called using \(\text{maj.rule} = \text{TRUE}\). In this case, the triple \(a-b-c\) is marked as ‘ambiguous’ if and only if \(b\) is in exactly 50 percent of such separating sets or no separating set was found. If \(b\) is in less than 50 percent of the separating sets it is set as a v-structure, and if in more than 50 percent it is set as a non v-structure (for more details see Colombo and Maathuis, 2014). Colombo and Maathuis (2014) showed that with both these modifications, the final skeleton and the decisions about the v-structures of the FCI algorithm are fully order-independent. 

Note that the order-dependence issues on the 10 orientation rules are still present, see Colombo and Maathuis (2014) for more details.

Value

An object of \code{class} \texttt{fciAlgo} (see \texttt{fciAlgo}) containing the estimated graph (in the form of an adjacency matrix with various possible edge marks), the conditioning sets that lead to edge removals (sepset) and several other parameters.

Class "fciAlgo" of FCI Algorithm Results

Description

This class of objects is returned by functions `fci()`, `rfci()`, `fciPlus`, and `dag2pag` and represent the estimated PAG (and sometimes properties of the algorithm). Objects of this class have methods for the functions `plot`, `show` and `summary`.

Usage

```r
## S4 method for signature 'fciAlgo'
show(object)
## S3 method for class 'fciAlgo'
print(x, amat = FALSE, zero.print = ",", ...) 
## S4 method for signature 'fciAlgo'
summary(object, amat = TRUE, zero.print = ",", ...) 
## S4 method for signature 'fciAlgo,ANY'
plot(x, y, main = NULL, ...) 
```

Arguments

- `x`, object: a "fciAlgo" object.
- `amat`: logical indicating if the adjacency matrix should be shown (printed) as well.
- `zero.print`: string for printing 0 (‘zero’) entries in the adjacency matrix.
- `y`: (generic `plot()` argument; unused).
- `main`: main title, not yet supported.
- `...`: optional further arguments (passed from and to methods).

Slots

The slots `call`, `n`, `max.ord`, `n.edgetests`, `sepset`, and `pMax` are inherited from class "gAlgo", see there.

In addition, "fciAlgo" has slots

- `amat`: adjacency matrix; for the coding of the adjacency matrix see `amatType`
- `allPdsep`: a list: the ith entry of this list contains Possible D-SEP of node number i.
- `n.edgetestsPdsep`: the number of new conditional independence tests (i.e., tests that were not done in the first part of the algorithm) that were performed while checking subsets of Possible D-SEP.
- `max.ordPdsep`: an integer: the maximum size of the conditioning sets used in the new conditional independence that were performed when checking subsets of Possible D-SEP.
Extends

Class "gAlgo".

Methods

plot  signature(x = "fciAlgo"): Plot the resulting graph
show  signature(object = "fciAlgo"): Show basic properties of the fitted object
summary signature(object = "fciAlgo"): Show details of the fitted object

Author(s)

Markus Kalisch and Martin Maechler

fciPlus  

Estimate a PAG by the FCI+ Algorithm

Description

Estimate a Partial Ancestral Graph (PAG) from observational data, using the FCI+ (Fast Causal Inference) Algorithm.

Usage

fciPlus(suffStat, indepTest, alpha, labels, p, verbose=TRUE)
Arguments

suffStat  sufficient statistics: A named list containing all necessary elements for the conditional independence decisions in the function indepTest.

indepTest  a function for testing conditional independence. The function is internally called as indepTest(x, y, S, suffStat), and tests conditional independence of x and y given S. Here, x and y are variables, and S is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). suffStat is a list with all relevant information, see above. The return value of indepTest() is the p-value of the test for conditional independence.

alpha  numeric significance level (in (0, 1)) for the individual conditional independence tests.

labels  (optional) character vector of variable (or “node”) names. Typically preferred to specifying p.

p  (optional) number of variables (or nodes). May be specified if labels are not, in which case labels is set to 1:p.

verbose  logical indicating if progress of the algorithm should be printed. The default is true, which used to be hard coded previously.

Details

A variation of FCI (Fast Causal Inference). For details, please see the references, and also fci.

Value

An object of class fciAlgo (see fciAlgo) containing the estimated graph (in the form of an adjacency matrix with various possible edge marks), the conditioning sets that lead to edge removals (sepset) and several other parameters.

Author(s)

Emilija Perkovic and Markus Kalisch (<kalisch@stat.math.ethz.ch>).

Examples

# Example without latent variables
# generate a random DAG (p = 7)
find.unsh.triple

Find all Unshielded Triples in an Undirected Graph

Description

Find all unshielded triples in an undirected graph, g, i.e., the ordered ((x, y, z) with x < z) list of all the triples in the graph.

Usage

find.unsh.triple(g, check=TRUE)

Arguments

g

adjacency matrix of type amat.cpdag representing the skeleton; since a skeleton consists only of undirected edges, g must be symmetric.

check

logical indicating that the symmetry of g should be checked.

Details

A triple of nodes x, y and z is “unshielded”, if (all of these are true):

(i) x and y are connected;
(ii) y and z are connected;
(iii) x and z are not connected.

Value

unshTripl
Matrix with 3 rows containing in each column an unshielded triple

unshVect
Vector containing the unique number for each column in unshTripl (for internal use only)
gac

Test If Set Satisfies Generalized Adjustment Criterion (GAC)

Description

This function tests if \( z \) satisfies the Generalized Adjustment Criterion (GAC) relative to \( (x, y) \) in the graph represented by adjacency matrix \( \text{amat} \) and interpreted as type (DAG, maximal PDAG, CPDAG, MAG, PAG). If yes, \( z \) can be used in covariate adjustment for estimating causal effects of \( x \) on \( y \).

Usage

gac(amat, x, y, z, type = "pag")

Arguments

\texttt{amat} \\
adjacency matrix of type \texttt{amat.cpdag} or \texttt{amat.pag}

\texttt{x, y, z} \\
(integer) positions of variables in \( x, y \) or \( z \) in the adjacency matrix. \( x, y \) and \( z \) can be vectors representing several nodes.

\texttt{type} \\
string specifying the type of graph of the adjacency matrix \texttt{amat}. It can be a DAG (type="dag"), a PDAG (type="pdag") or a CPDAG (type="cpdag"); then the type of the adjacency matrix is assumed to be \texttt{amat.cpdag}. It can also be a MAG (type="mag"), or a PAG (type="pag"); then the type of the adjacency matrix is assumed to be \texttt{amat.pag}.

Examples

data(gmG)
if (require(Rgraphviz)) {
## show graph
plot(gmG$s, main = "True DAG")
}

## prepare skeleton use in example
G <- wgtMatrix(gmG$s) ## compute weight matrix
G <- 1 * (g != 0) # wghts --> 0/1; still lower triangular
print.table(G, zero.print = ".")
skel <- G + t(G) ## adjacency matrix of skeleton

## estimate unshielded triples -- there are 13:
(uTr <- find.unsh.triple(skel))
Details

This work is a generalization of the work of Shpitser et al. (2012) (necessary and sufficient criterion in DAGs/ADMGs) and van der Zander et al. (2014) (necessary and sufficient criterion in MAGs). Moreover, it is a generalization of the Generalized Backdoor Criterion (GBC) of Maathuis and Colombo (2013): While GBC is sufficient but not necessary, GAC is both sufficient and necessary for DAGs, CPDAGs, MAGs and PAGs. For more details see Perkovic et al. (2015, 2017a, 2017b).

The motivation to find a set \( z \) that satisfies the GAC with respect to \( (x, y) \) is the following:

A set of variables \( z \) satisfies the GAC relative to \( (x, y) \) in the given graph, if and only if the causal effect of \( x \) on \( y \) is identifiable by covariate adjustment and is given by

\[
P(Y|do(X = x)) = \sum_{Z} P(Y|X, Z) \cdot P(Z),
\]

(for any joint distribution “compatible” with the graph; the formula is for discrete variables with straightforward modifications for continuous variables). This result allows to write post-intervention densities (the one written using Pearl’s do-calculus) using only observational densities estimated from the data.

For \( z \) to satisfy the GAC relative to \( (x, y) \) and the graph, the following three conditions must hold:

1. The graph is adjustment amenable relative to \( (x, y) \).
2. The intersection of \( z \) and the forbidden set (explained in Perkovic et al. (2015, 2017b)) is empty.
3. All proper definite status non-causal paths in the graph from \( x \) to \( y \) are blocked by \( z \).

It is important to note that there can be \( x \) and \( y \) for which there is no set \( Z \) that satisfies the GAC, but the total causal effect might be identifiable via some technique other than covariate adjustment.

For details on the GAC for DAGs, CPDAGs, PAGs see Perkovic et al. (2015, 2017a). For details on the GAC for MAGs see van der Zander et al. (2014) and for details on the GAC for maximal PDAGs see Perkovic et al. (2017b).

For the coding of the adjacency matrix see amatType. The input matrix can either be of class matrix or of class amat.

Value

A list with three components:

- gac: logical; TRUE if \( z \) satisfies the GAC relative to \( (x, y) \) in the graph represented by amat and type
- res: logical vector of length three indicating if each of the three conditions (0), (1) and (2) are true
- f: node positions of nodes in the forbidden set (see Perkovic et al. (2015, 2017b))

## Example 4.7 in Perkovic et. al (2017b)
gAlgo-class

### Description

"gAlgo" is a "VIRTUAL" class, the common basis of classes "pcAlgo" and "fciAlgo".

We describe the common slots here; for more see the help pages of the specific classes.

### Slots

- **call**: a call object: the original function call.
- **n**: an "integer", the sample size used to estimate the graph.
- **max. ord**: an integer, the maximum size of the conditioning set used in the conditional independence tests of the (first part of the algorithm), in function skeleton.
- **n.edgetests**: the number of conditional independence tests performed by the (first part of the) algorithm.
- **sepset**: a list, the conditioning sets that led to edge deletions. The set that led to the removal of the edge i −− j is saved in either sepset[[i]][[j]] or in sepset[[j]][[i]].
- **pMax**: a numeric square matrix, where the (i,j)th entry contains the maximal p-value of all conditional independence tests for edge i −− j.

### Author(s)

Martin Maechler

"pcAlgo" and "fciAlgo".

### Examples

```
showClass("gAlgo")
```
This class represents a score for causal inference from jointly interventional and observational Gaussian data; it is used in the causal inference functions `gies` and `simy`.

The class implements an $\ell_0$-penalized Gaussian maximum likelihood estimator. The penalization is a constant (specified by the argument `lambda` in the constructor) times the number of parameters of the DAG model. By default, the constant $\lambda$ is chosen as $\log(n)/2$, which corresponds to the BIC score.

Class "Score", directly.
All reference classes extend and inherit methods from "envRefClass".

The class `GaussL0penIntScore` has the same fields as `Score`. They need not be accessed by the user.

**Constructor**

```r
new("GaussL0penIntScore",
     data = matrix(1, 1, 1),
     targets = list(integer(0)),
     target.index = rep(as.integer(1), nrow(data)),
     lambda = 0.5*log(nrow(data)),
     intercept = FALSE,
     use.cpp = TRUE,
     ...
)
```

- **data** Data matrix with $n$ rows and $p$ columns. Each row corresponds to one realization, either interventional or observational.
- **targets** List of mutually exclusive intervention targets that have been used for data generation.
- **target.index** Vector of length $n$; the $i$-th entry specifies the index of the intervention target in targets under which the $i$-th row of data was measured.
- **lambda** Penalization constant (cf. details)
- **intercept** Indicates whether an intercept is allowed in the linear structural equations, or, equivalently, if a mean different from zero is allowed for the observational distribution.
use.Ncpp Indicates whether the calculation of the score should be done by the C++ library of the package, which speeds up calculation. This parameter should only be set to FALSE in the case of problems.

Methods

local.score(vertex, parents, ...) Calculates the local score of a vertex and its parents. Since this score has no obvious interpretation, it is rather for internal use.

global.score.int(edges, ...) Calculates the global score of a DAG, represented as a list of in-edges: for each vertex in the DAG, this list contains a vector of parents.

global.score(dag, ...) Calculates the global score of a DAG, represented as an object of a class derived from ParDAG.

local.mle(vertex, parents, ...) Calculates the local MLE of a vertex and its parents. The result is a vector of parameters encoded as follows:

• First element: variance of the Gaussian error term
• Second element: intercept
• Following elements: regression coefficients; one per parent vertex

global.mle(dag, ...) Calculates the global MLE of a DAG, represented by an object of a class derived from ParDAG. The result is a list of vectors, one per vertex, each in the same format as the result vector of local.mle.

GaussParDAG-class  

Class "GaussParDAG" of Gaussian Causal Models

Description

The "GaussParDAG" class represents a Gaussian causal model.

Details

The class "GaussParDAG" is used to simulate observational and/or interventional data from Gaussian causal models as well as for parameter estimation (maximum-likelihood estimation) for a given DAG structure in the presence of a data set with jointly observational and interventional data.

A Gaussian causal model can be represented as a set of \( p \) linear structural equations with Gaussian noise variables. Those equations are fully specified by indicating the regression parameters, the intercept and the variance of the noise or error terms. More details can be found e.g. in Kalisch and Bühlmann (2007) or Hauser and Bühlmann (2012).

Extends

Class "ParDAG", directly.

All reference classes extend and inherit methods from "envRefClass".

Constructor

```
new("GaussParDAG", nodes, in.edges, params)
```

- `nodes` Vector of node names; cf. also field .nodes.
- `in.edges` A list of length \( p \) consisting of index vectors indicating the edges pointing into the nodes of the DAG.
- `params` A list of length \( p \) consisting of parameter vectors modeling the conditional distribution of a node given its parents; cf. also field .params for the meaning of the parameters.

Fields

- `.nodes`: Vector of node names; defaults to as.character(1:p), where \( p \) denotes the number of nodes (variables) of the model.
- `.in.edges`: A list of length \( p \) consisting of index vectors indicating the edges pointing into the nodes of the DAG. The \( i \)-th entry lists the indices of the parents of the \( i \)-th node.
- `.params`: A list of length \( p \) consisting of parameter vectors modeling the conditional distribution of a node given its parents. The \( i \)-th entry models the conditional (normal) distribution of the \( i \)-th variable in the model given its parents. It is a vector of length \( k + 2 \), where \( k \) is the number of parents of node \( i \); the first entry encodes the error variance of node \( i \), the second entry the intercept, and the remaining entries the regression coefficients (see above). In most cases, it is easier to access the parameters via the wrapper functions err.var, intercept and weight.mat.
Class-Based Methods

`set.err.var(value)`: Sets the error variances. The argument must be a vector of length \( p \), where \( p \) denotes the number of nodes in the model.

`err.var()`: Yields the vector of error variances.

`intercept()`: Yields the vector of intercepts.

`set.intercept(value)`: Sets the intercepts. The argument must be a vector of length \( p \), where \( p \) denotes the number of nodes in the model.

`weight.mat(target)`: Yields the (observational or interventional) weight matrix of the model. The weight matrix is an \( p \times p \) matrix whose \( i \)-th columns contains the regression coefficients of the \( i \)-th structural equation, if node \( i \) is not intervened (i.e., if \( i \) is not contained in the vector `target`), and is empty otherwise.

`cov.mat(target,ivent.var)`: Yields the covariance matrix of the observational or an interventional distribution of the causal model. If `target` has length 0, the covariance matrix of the observational distribution is returned; otherwise `target` is a vector of the intervened nodes, and `ivent.var` is a vector of the same length indicating the variances of the intervention levels. Deterministic interventions with fix intervention levels would correspond to vanishing intervention variances; with non-zero intervention variances, stochastic interventions are considered in which intervention values are realizations of Gaussian variables (Korb et al., 2004).

The following methods are inherited (from the corresponding class): `node.count` ("ParDAG"), `edge.count` ("ParDAG"), `simulate` ("ParDAG")

gds

**Greedy DAG Search to Estimate Markov Equivalence Class of DAG**

**Description**

Estimate the observational or interventional essential graph representing the Markov equivalence class of a DAG by greedily optimizing a score function in the space of DAGs. In practice, greedy search should always be done in the space of equivalence classes instead of DAGs, giving the functions gies or ges the preference over gds.

**Usage**

```r
mydag = gds(score = score, labels = score$getNodeNames(), targets = score$getInterventionTargets(),
fixedGaps = NULL, phase = c("forward", "backward", "turning"),
iterate = length(phase) > 1, turning = TRUE, maxDegree = integer(0),
verbose = FALSE, ...)
```

**Arguments**

- **score**
  An instance of a class derived from `Score`.
- **labels**
  Node labels; by default, they are determined from the scoring object.
- **targets**
  A list of intervention targets (cf. details). A list of vectors, each vector listing the vertices of one intervention target.
- **fixedGaps**
  Logical symmetric matrix of dimension p*p. If entry [i, j] is TRUE, the result is guaranteed to have no edge between nodes i and j.
- **phase**
  Character vector listing the phases that should be used; possible values: forward, backward, and turning (cf. details).
- **iterate**
  Logical indicating whether the phases listed in the argument phase should be iterated more than once (iterate = TRUE) or not.
- **turning**
  Setting turning = TRUE is equivalent to setting phases = c("forward", "backward") and iterate = FALSE; the use of the argument turning is deprecated.
- **maxDegree**
  Parameter used to limit the vertex degree of the estimated graph. Valid arguments:
  1. Vector of length 0 (default): vertex degree is not limited.
  2. Real number r, 0 < r < 1: degree of vertex v is limited to r · n_v, where n_v denotes the number of data points where v was not intervened.
3. Single integer: uniform bound of vertex degree for all vertices of the graph.
4. Integer vector of length \(p\): vector of individual bounds for the vertex degrees.

`verbose` if `TRUE`, detailed output is provided.

... additional arguments for debugging purposes and fine tuning.

**Details**

This function estimates the observational or interventional Markov equivalence class of a DAG based on a data sample with interventional data originating from various interventions and possibly observational data. The intervention targets used for data generation must be specified by the argument `targets` as a list of (integer) vectors listing the intervened vertices; observational data is specified by an empty set, i.e. a vector of the form `integer(0)`. As an example, if data contains observational samples as well as samples originating from an intervention at vertices 1 and 4, the intervention targets must be specified as `list(integer(0), as.integer(1), as.integer(c(1, 4)))`.

An interventional Markov equivalence class of DAGs can be uniquely represented by a partially directed graph called interventional essential graph. Its edges have the following interpretation:

1. a directed edge \(a \rightarrow b\) stands for an arrow that has the same orientation in all representatives of the interventional Markov equivalence class;
2. an undirected edge \(a - b\) stands for an arrow that is oriented in one way in some representatives of the equivalence class and in the other way in other representatives of the equivalence class.

Note that when plotting the object, undirected and bidirected edges are equivalent.

Greedy DAG search (GDS) maximizes a score function (typically the BIC, passed to the function via the argument `score`) of a DAG in three phases, starting from the empty DAG:

**Forward phase** In the forward phase, GDS adds single arrows to the DAG as long as this augments the score.

**Backward phase** In the backward phase, the algorithm removes arrows from the DAG as long as this augments the score.

**Turning phase** In the turning phase, the algorithm reverts arrows of the DAG as long as this augments the score.

The phases that are actually run are specified with the argument `phase`. GDS cycles through the specified phases until no augmentation of the score is possible any more if `iterate = TRUE`. In the end, `gds` returns the (interventional or observational) essential graph of the last visited DAG.

It is well-known that a greedy search in the space of DAGs instead of essential graphs is more prone to be stuck in local optima of the score function and hence expected to yield worse estimation results than GIES (function `gies`) or GES (function `ges`) (Chickering, 2002; Hauser and Bühlmann, 2012). The function `gds` is therefore not of practical use, but can be used to compare causal inference algorithms to an elementary and straight-forward approach.

**Value**

gds returns a list with the following two components:

`essgraph` An object of class `EssGraph` containing an estimate of the equivalence class of the underlying DAG.
ges

An object of a class derived from ParDAG containing a (random) representative of the estimated equivalence class.

```

Description

Estimate the Markov equivalence class of a DAG using GES

Estimate the observational essential graph representing the Markov equivalence class of a DAG using the greedy equivalence search (GES) algorithm of Chickering (2002).
Usage

ges(score, labels = score$getNodes(),
    fixedGaps = NULL, adaptive = c("none", "vstructures", "triples"),
    phase = c("forward", "backward", "turning"), iterate = length(phase) > 1,
    turning = NULL, maxDegree = integer(0), verbose = FALSE, ...)

Arguments

score An instance of a class derived from Score which only accounts for observational data. If the dataset is high-dimensional (p>=n) ges might not be able to terminate.
labels Node labels; by default, they are determined from the scoring object.
fixedGaps logical symmetric matrix of dimension p*p. If entry [i, j] is TRUE, the result is guaranteed to have no edge between nodes i and j.
adaptive indicating whether constraints should be adapted to newly detected v-structures or unshielded triples (cf. details).
phase Character vector listing the phases that should be used; possible values: forward, backward, and turning (cf. details).
iterate Logical indicating whether the phases listed in the argument phase should be iterated more than once (iterate = TRUE) or not.
turning Setting turning = TRUE is equivalent to setting phases = c("forward", "backward") and iterate = FALSE; the use of the argument turning is deprecated.
maxDegree Parameter used to limit the vertex degree of the estimated graph. Valid arguments:
   1. Vector of length 0 (default): vertex degree is not limited.
   2. Real number \( r, 0 < r < 1 \): degree of vertex \( v \) is limited to \( r \cdot n_v \), where \( n_v \) denotes the number of data points where \( v \) was not intervened.
   3. Single integer: uniform bound of vertex degree for all vertices of the graph.
   4. Integer vector of length p: vector of individual bounds for the vertex degrees.
verbose If TRUE, detailed output is provided.
...
... Additional arguments for debugging purposes and fine tuning.

Details

Under the assumption that the distribution of the observed variables is faithful to a DAG, this function estimates the Markov equivalence class of the DAG. It does not estimate the DAG itself, because this is typically impossible (even with an infinite amount of data): different DAGs (forming a Markov equivalence class) can describe the same conditional independence relationships and be statistically indistinguishable from observational data alone.

All DAGs in an equivalence class have the same skeleton (i.e., the same adjacency information) and the same v-structures (i.e., the same induced subgraphs of the form \( a \rightarrow b \leftarrow c \)). However, the direction of some edges may be undetermined, in the sense that they point one way in one DAG in the equivalence class, while they point the other way in another DAG in the equivalence class.
An equivalence class can be uniquely represented by a partially directed graph called (observational) essential graph or CPDAG (completed partially directed acyclic graph). Its edges have the following interpretation:

1. a directed edge \( a \rightarrow b \) stands for an arrow that has the same orientation in all representatives of the Markov equivalence class;
2. an undirected edge \( a - b \) stands for an arrow that is oriented in one way in some representatives of the equivalence class and in the other way in other representatives of the equivalence class.

Note that when plotting the object, undirected and bidirected edges are equivalent.

GES (greedy equivalence search) is a score-based algorithm that greedily maximizes a score function (typically the BIC, passed to the function via the argument \( \text{score} \)) in the space of (observational) essential graphs in three phases, starting from the empty graph:

**Forward phase** In the forward phase, GES moves through the space of essential graphs in steps that correspond to the addition of a single edge in the space of DAGs; the phase is aborted as soon as the score cannot be augmented any more.

**Backward phase** In the backward phase, the algorithm performs moves that correspond to the removal of a single edge in the space of DAGs until the score cannot be augmented any more.

**Turning phase** In the turning phase, the algorithm performs moves that correspond to the reversal of a single arrow in the space of DAGs until the score cannot be augmented any more.

GES cycles through these three phases until no augmentation of the score is possible any more if iterate = \text{TRUE}. Note that the turning phase was not part of the original implementation of Chickering (2002), but was introduced by Hauser and Bühlmann (2012) and shown to improve the overall estimation performance. The original algorithm of Chickering (2002) is reproduced with phase = c("forward", "backward") and iterate = FALSE.

GES has the same purpose as the PC algorithm (see \text{pc}). While the PC algorithm is based on conditional independence tests (requiring the choice of an independence test and a significance level, see \text{pc}), the GES algorithm is a score-based method (requiring the choice of a score function) and does not depend on conditional independence tests. Since GES always operates in the space of essential graphs, it returns a valid essential graph (or CPDAG) in any case.

Using the argument \text{fixedGaps}, one can make sure that certain edges will not be present in the resulting essential graph: if the entry \([i, j]\) of the matrix passed to \text{fixedGaps} is \text{TRUE}, there will be no edge between nodes \(i\) and \(j\). Using this argument can speed up the execution of GIES and allows the user to account for previous knowledge or other constraints. The argument \text{adaptive} can be used to relax the constraints encoded by \text{fixedGaps} according to a modification of GES called ARGES (adaptively restricted greedy equivalence search) which has been presented in Nandy, Hauser and Maathuis (2015):

- When adaptive = "vstructures" and the algorithm introduces a new v-structure \( a \rightarrow b \leftarrow c \) in the forward phase, then the edge \( a - c \) is removed from the list of fixed gaps, meaning that the insertion of an edge between \(a\) and \(c\) becomes possible even if it was forbidden by the initial matrix passed to \text{fixedGaps}.
- When adaptive = "triples" and the algorithm introduces a new unshielded triple in the forward phase (i.e., a subgraph of three nodes \(a, b\) and \(c\) where \(a\) and \(b\) as well as \(b\) and \(c\) are adjacent, but \(a\) and \(c\) are not), then the edge \(a - c\) is removed from the list of fixed gaps.
With one of the adaptive modifications, the successive application of a skeleton estimation method and GES restricted to an estimated skeleton still gives a consistent estimator of the DAG, which is not the case without the adaptive modification.

Value

ges returns a list with the following two components:

- `essgraph`: An object of class `EssGraph` containing an estimate of the equivalence class of the underlying DAG.
- `repr`: An object of a class derived from `ParDAG` containing a (random) representative of the estimated equivalence class.

getGraph

Get the "graph" Part or Aspect of R Object

Description

Get the graph part or “aspect” of an R object, notably from our pc(), skeleton(), fci(), etc, results.

Usage

getGraph(x)

Arguments

x potentially any R object which can be interpreted as a graph (with nodes and edges).

Value

a graph object, i.e., one inheriting from (the virtual) class "graph", package graph.

Methods

signature(x = "ANY") the default method just tries as(x, "graph"), so works when a coerce (S4) method is defined for x.
signature(x = "pcAlgo") and
signature(x = "fciAlgo") extract the graph part explicitly.
signature(x = "matrix") interpret x as adjacency matrix and return the corresponding "graphAM" object.

For sparseMatrix methods, see the ‘Note’.

Note

For large graphs, it may be attractive to work with sparse matrices from the Matrix package. If desired, you can activate this by

require(Matrix)
setMethod("getGraph", "sparseMatrix", function(x) as(x, "graphNEL"))
setMethod("getGraph", "Matrix", function(x) as(x, "graphAM"))

Examples

```r
A <- rbind(c(0,1,0,0,1),
            c(0,0,0,1,1),
            c(1,0,0,1,0),
            c(1,0,0,0,1),
            c(0,0,0,1,0))
sum(A) # 9
getGraph(A) ## a graph with 5 nodes and 'sum(A)' edges
```

### `getNextSet`

**Iteration through a list of all combinations of choose(n,k)**

#### Description

Given a combination of \( k \) elements out of the elements \( 1, \ldots, n \), the next set of size \( k \) in a specified sequence is computed.

#### Usage

```r
getNextSet(n,k,set)
```

#### Arguments

- `n` Number of elements to choose from (integer)
- `k` Size of chosen set (integer)
- `set` Previous set in list (numeric vector)

#### Details

The initial set is \( 1:k \). Last index varies quickest. Using the dynamic creation of sets reduces the memory demands dramatically for large sets. If complete lists of combination sets have to be produced and memory is no problem, the function `combn` from package `combinat` is an alternative.

#### Value

List with two elements:
- `nextSet` Next set in list (numeric vector)
- `wasLast` Logical indicating whether the end of the specified sequence is reached.

Estimate Interventional Markov Equivalence Class of a DAG by GIES

Description

Estimate the interventional essential graph representing the Markov equivalence class of a DAG using the greedy interventional equivalence search (GIES) algorithm of Hauser and Bühlmann (2012).

Usage

```r
gies(score, labels = score$getNodes(), targets = score$getTargets(),
     fixedGaps = NULL, adaptive = c("none", "vstructures", "triples"),
     phase = c("forward", "backward", "turning"), iterate = length(phase) > 1,
     turning = NULL, maxDegree = integer(0), verbose = FALSE, ...)
```

Arguments

- `score` An R object inheriting from `Score`.
- `labels` Node labels; by default, they are determined from the scoring object.
targets A list of intervention targets (cf. details). A list of vectors, each vector listing the vertices of one intervention target.

fixedGaps Logical symmetric matrix of dimension p*p. If entry [i, j] is TRUE, the result is guaranteed to have no edge between nodes i and j.

adaptive indicating whether constraints should be adapted to newly detected v-structures or unshielded triples (cf. details).

phase Character vector listing the phases that should be used; possible values: forward, backward, and turning (cf. details).

iterate Logical indicating whether the phases listed in the argument phase should be iterated more than once (iterate = TRUE) or not.

turning Setting turning = TRUE is equivalent to setting phases = c("forward", "backward") and iterate = FALSE; the use of the argument turning is deprecated.

maxDegree Parameter used to limit the vertex degree of the estimated graph. Possible values:
1. Vector of length 0 (default): vertex degree is not limited.
2. Real number $r$, $0 < r < 1$: degree of vertex $v$ is limited to $r \cdot n_v$, where $n_v$ denotes the number of data points where $v$ was not intervened.
3. Single integer: uniform bound of vertex degree for all vertices of the graph.
4. Integer vector of length $p$: vector of individual bounds for the vertex degrees.

verbose If TRUE, detailed output is provided.

... Additional arguments for debugging purposes and fine tuning.

Details

This function estimates the interventional Markov equivalence class of a DAG based on a data sample with interventional data originating from various interventions and possibly observational data. The intervention targets used for data generation must be specified by the argument targets as a list of (integer) vectors listing the intervened vertices; observational data is specified by an empty set, i.e. a vector of the form integer(0). As an example, if data contains observational samples as well as samples originating from an intervention at vertices 1 and 4, the intervention targets must be specified as list(integer(0), as.integer(1), as.integer(c(1, 4))).

An interventional Markov equivalence class of DAGs can be uniquely represented by a partially directed graph called interventional essential graph. Its edges have the following interpretation:

1. a directed edge $a \rightarrow b$ stands for an arrow that has the same orientation in all representatives of the interventional Markov equivalence class;

2. an undirected edge $a - b$ stands for an arrow that is oriented in one way in some representatives of the equivalence class and in the other way in other representatives of the equivalence class.

Note that when plotting the object, undirected and bidirected edges are equivalent.

GIES (greedy interventional equivalence search) is a score-based algorithm that greedily maximizes a score function (typically the BIC, passed to the function via the argument score) in the space of interventional essential graphs in three phases, starting from the empty graph:

...
**Forward phase**  In the forward phase, GIES moves through the space of interventional essential graphs in steps that correspond to the addition of a single edge in the space of DAGs; the phase is aborted as soon as the score cannot be augmented any more.

**Backward phase**  In the backward phase, the algorithm performs moves that correspond to the removal of a single edge in the space of DAGs until the score cannot be augmented any more.

**Turning phase**  In the turning phase, the algorithm performs moves that correspond to the reversal of a single arrow in the space of DAGs until the score cannot be augmented any more.

The phases that are actually run are specified with the argument `phase`. GIES cycles through the specified phases until no augmentation of the score is possible any more if `iterate = TRUE`. GIES is an interventional extension of the GES (greedy equivalence search) algorithm of Chickering (2002) which is limited to observational data and hence operates on the space of observational instead of interventional Markov equivalence classes.

Using the argument `fixedgaps`, one can make sure that certain edges will *not* be present in the resulting essential graph: if the entry \([i, j]\) of the matrix passed to `fixedgaps` is `TRUE`, there will be no edge between nodes \(i\) and \(j\). Using this argument can speed up the execution of GIES and allows the user to account for previous knowledge or other constraints. The argument `adaptive` can be used to relax the constraints encoded by `fixedgaps` as follows:

- When `adaptive = "vstructures"` and the algorithm introduces a new v-structure \(a \rightarrow b \leftarrow c\) in the forward phase, then the edge \(a \rightarrow c\) is removed from the list of fixed gaps, meaning that the insertion of an edge between \(a\) and \(c\) becomes possible even if it was forbidden by the initial matrix passed to `fixedgaps`.

- When `adaptive = "triples"` and the algorithm introduces a new unshielded triple in the forward phase (i.e., a subgraph of three nodes \(a\), \(b\), and \(c\) where \(a\) and \(b\) as well as \(b\) and \(c\) are adjacent, but \(a\) and \(c\) are not), then the edge \(a \rightarrow c\) is removed from the list of fixed gaps.

This modifications of the forward phase of GIES are inspired by the analog modifications in the forward phase of GES, which makes the successive application of a skeleton estimation method and GES restricted to an estimated skeleton a *consistent* estimator of the DAG (cf. Nandy, Hauser and Maathuis, 2015).

**Value**

gies returns a list with the following two components:

- `essgraph`  An object of class `EssGraph` containing an estimate of the equivalence class of the underlying DAG.

- `repr`  An object of a class derived from `ParDAG` containing a (random) representative of the estimated equivalence class.

### gmB

**Graphical Model 5-Dim Binary Example Data**

Description

This data set contains a matrix containing information on five binary variables (coded as 0/1) and the corresponding DAG model.

Usage

```r
data(gmB)
```
Format

The format is a list of two components

\( x: \) Int \([1:5000, 1:5]\) 0 1 1 0 0 1 1 0 1 1 ...

\( g: \) Formal class 'graphNEL' [package "graph"] with 6 slots
  .. .@ nodes : chr \([1:5]\) "1" "2" "3" "4" ...
  .. .@ edgeL :List of 5

Details

The data was generated using Tetrad in the following way. A random DAG on five nodes was generated; binary variables were assigned to each node; then conditional probability tables corresponding to the structure of the generated DAG were constructed. Finally, 5000 samples were drawn using the conditional probability tables.

Examples

```r
data(gmB)
### maybe str(gmB) ; plot(gmB) ...
```

Description

This data set contains a matrix containing information on five discrete variables (levels are coded as numbers) and the corresponding DAG model.

Usage

```r
data(gmD)
```

Format

A list of two components

\( x: \) a `data.frame` with 5 columns `X1` .. `X5` each coding a discrete variable (aka `factor`) with integers `Int [1:10000, 1:5] 2 2 1 1 2 2 0 2 0 ...

**gmG**

*Graphical Model 8-Dimensional Gaussian Example Data*

Description

These two data sets contain a matrix containing information on eight gaussian variables and the corresponding DAG model.

Usage

data(gmG)

Format

gmG and gmG8 are each a **list** of two components

**x**: a numeric matrix $5000 \times 8$. 
g: a graph, i.e., of formal **class** "graphNEL" from package **graph** with 6 slots
  .. ..@ nodes : chr [1:8] "1" "2" "3" "4" ...
  .. ..@ edgeL : List of 8
  .......

**Details**

The data was generated as indicated below. First, a random DAG model was generated, then 5000 samples were drawn from “almost” this model, for **gmg**: In the previous version, the data generation **wgtMatrix** had the non-zero weights in reversed order for each node. On the other hand, for **gmG8**, the correct weights were used in all cases

**Source**

The data set is **identical** to the one generated by

```r
## Used to generate "gmg"
set.seed(40)
p <- 8
n <- 5000
## true DAG:
vars <- c("Author", "Bar", "Ctrl1", "Goal", paste0("V",5:8))
gGtrue <- randomDAG(p, prob = 0.3, V = vars)
gmg <- list(x = rmvDAG(n, gGtrue, back.compatible=TRUE), g = gGtrue)
gmG8 <- list(x = rmvDAG(n, gGtrue), g = gGtrue)
```

**Examples**

```r
data(gmg)
str(gmg, max=3)
stopifnot(identical(gmg $ g, gmG8 $ g))
if(dev.interactive()) { ## to save time in tests
round(as(gmg $ g, "Matrix"), 2) # weight ("adjacency") matrix
plot(gmg $ g)
pairs(gmG8x, gap = 0, panel=function(...) smoothScatter(..., add=TRUE))
}
```

---

**Description**

This data set contains a matrix containing information on seven gaussian variables and the corresponding DAG model.
Usage

data(gmI)

Format

The two gmI* objects are each a list of two components x, an \( n \times 7 \) numeric matrix, and g, a DAG, a graph generated by \texttt{randomDAG}.

See \texttt{gmG} for more.

Details

The data was generated as indicated below. First, a random DAG was generated, then samples were drawn from this model, strictly speaking for gmI7 only.

Source

The data sets are \texttt{identical} to those generated by

```r
## Used to generate "gmI"
set.seed(123)
p <- 7
myDAG <- randomDAG(p, prob = 0.2) ## true DAG
gmI <- list(x = rmvDAG(10000, myDAG, back.compatible=TRUE), g = myDAG)
gmI7 <- list(x = rmvDAG(8000, myDAG), 
             g = myDAG)
```

Examples

```r
data(gmI)
str(gmI, max=3)
stopifnot(identical(gmI $ g, gmI7 $ g))
if(dev.interactive()) { ## to save time in tests
  round(as(gmI $ g, "Matrix"), 2) # weight ("adjacency") matrix
  plot(gmI $ g)
  pairs(gmI$x, gap = 0,
       panel=function(...) smoothScatter(..., add=TRUE))
}
```

Description

This data set contains a matrix with an ensemble of observational and interventional data from eight Gaussian variables. The corresponding (data generating) DAG model is also stored.
Usage

data(gmInt)

Format

The format is a list of four components:

- **x**: Matrix with 5000 rows (one row a measurement) and 8 columns (corresponding to the 8 variables targets).
- **targets**: List of (mutually exclusive) intervention targets. In this example, the three entries integer(0), 3 and 5 indicate that the data set consists of observational data, interventional data originating from an intervention at vertex 3, and interventional data originating from an intervention at vertex 5.
- **target.index**: Vector with 5000 elements. Each entry maps a row of x to the corresponding intervention target. Example: `gmInt$target.index[3322] == 2` means that x[3322, ] was simulated from an intervention at `gmInt$targets[[2]]`, i.e. at vertex 3.
- **g**: Formal class `graphNEL` [package “graph”] with 6 slots, representing the true DAG from which observational and interventional data was sampled.

Details

The data was generated as indicated below. First, a random DAG model was generated, then 5000 samples were drawn from this model: 3000 observational ones, and 1000 each from an intervention at vertex 3 and 5, respectively (see `gmInt$target.index`).

Source

The data set is identical to the one generated by

```r
set.seed(40)
p <- 8
n <- 5000
gGtrue <- randomDAG(p, prob = 0.3)
pardag <- as(gGtrue, "GaussParDAG")
pardag$set.err.var(rep(1, p))
targets <- list(integer(0), 3, 5)
target.index <- c(rep(1, 0.6*n), rep(2, n/5), rep(3, n/5))
x1 <- rmvnorm.vent(0.6*n, pardag)
x2 <- rmvnorm.vent(n/5, pardag, targets[[2]], matrix(rnorm(n/5, mean = 4, sd = 0.02), ncol = 1))
x3 <- rmvnorm.vent(n/5, pardag, targets[[3]], matrix(rnorm(n/5, mean = 4, sd = 0.02), ncol = 1))
gmInt <- list(x = rbind(x1, x2, x3), targets = targets, target.index = target.index, g = gGtrue)
```
Examples

data(gmlInt)
str(gmlInt, max = 3)
pairs(gmlInt$x, gap = 0, pch = ".")

Description

This data set contains a matrix containing information on four gaussian variables and the corresponding DAG model containing four observed and one latent variable.

Usage

data(gmL)

Format

The format is a list of 2 components

x: $ x: num [1:10000, 1:4] 0.924 -0.189 1.016 0.363 0.497 ... ..- attr(*, "dimnames")=List of 2 .. ..$ : NULL .. ..$ : chr [1:4] "2" "3" "4" "5"

$ g: Formal class 'graphNEL' [package "graph"] with 6 slots .. .. @ nodes : chr [1:5] "1" "2" "3" "4" .. .. @ edgeL :List of 5 .......

Details

The data was generated as indicated below. First, a random DAG model was generated with five nodes; then 10000 samples were drawn from this model; finally, variable one was declared to be latent and the corresponding column was deleted from the simulated data set.

Source

```r
## Used to generate "gmL"
set.seed(47)
p <- 5
n <- 10000
gTrue <- randomDAG(p, prob = 0.3) ## true DAG
myX <- rmvDAG(n, gTrue)
colnames(myX) <- as.character(1:5)
gmL <- list(x = myX[,-1], g = gTrue)
```
Examples

\begin{verbatim}
data(gml)
str(gml, max=3)

## the graph:
gml$g
graph::nodes(gml$g) ; str(graph::edges(gml$g))
if(require("Rgraphviz"))
  plot(gml$g, main = "gml $ g -- latent variable example data")
pairs(gml$x) # the data
\end{verbatim}

ida

Estimate Multiset of Possible Total Causal Effects

Description

ida() estimates the multiset of possible total causal effects of one variable (x) onto another variable (y) from observational data.

causalEffect(g, y, x) computes the true causal effect ($\beta_{\text{true}}$) of x on y in g.

Usage

\begin{verbatim}
ida(x.pos, y.pos, mcov, graphest, method = c("local","global"),
y.notparent = FALSE, verbose = FALSE, all.dags = NA, type = c("cpdag", "pdag"))
\end{verbatim}

causalEffect(g, y, x)

Arguments

- `x.pos`: (integer) position of variable x in the covariance matrix.
- `y.pos`: (integer) position of variable y in the covariance matrix.
- `mcov`: Covariance matrix that was used to estimate `graphEst`.
- `graphEst`: Estimated CPDAG or PDAG. The CPDAG is typically from `pc()`: If the result of `pc` is `pc.fit`, the estimated CPDAG can be obtained by `pc.fit@graph`. The PDAG can be obtained from CPDAG by adding background knowledge using `addBgKnowledge()`.
- `method`: Character string specifying the method with default "local".
  - "global": The algorithm considers all DAGs in the represented by the CPDAG or PDAG, hence is slow.
  - "local": The algorithm only considers the neighborhood of x in the CPDAG or PDAG, hence is faster.
  See details below.
- `y.notparent`: Logical; if true, any edge between x and y is assumed to be of the form x->y.
If TRUE, details on the regressions are printed.

All DAGs in the equivalence class represented by the CPDAG or PDAG can be precomputed by `pdag2allDags()` and passed via this argument. In that case, `pdag2allDags(...)` is not called internally. This option is only relevant when using `method="global"`.

Graph in which the causal effect is sought.

Type of graph "graphEst": can be of type "cpdag" or "pdag" (e.g. a CPDAG with background knowledge from Meek, 1995)

Details

It is assumed that we have observational data that are multivariate Gaussian and faithful to the true (but unknown) underlying causal DAG (without hidden variables). Under these assumptions, this function estimates the multiset of possible total causal effects of \( x \) on \( y \), where the total causal effect is defined via Pearl’s do-calculus as

\[
E(Y|do(X = z + 1)) - E(Y|do(X = z))
\]

(this value does not depend on \( z \), since Gaussianity implies that conditional expectations are linear).

We estimate a set of possible total causal effects instead of the unique total causal effect, since it is typically impossible to identify the latter when the true underlying causal DAG is unknown (even with an infinite amount of data). Conceptually, the method works as follows. First, we estimate the equivalence class of DAGs that describe the conditional independence relationships in the data, using the function `pc` (see the help file of this function). For each DAG \( G \) in the equivalence class, we apply Pearl’s do-calculus to estimate the total causal effect of \( x \) on \( y \). This can be done via a simple linear regression: if \( y \) is not a parent of \( x \), we take the regression coefficient of \( x \) in the regression \( lmHy ~ x \ K pa(x) \), where \( pa(x) \) denotes the parents of \( x \) in the DAG \( G \); if \( y \) is a parent of \( x \) in \( G \), we set the estimated causal effect to zero.

If the equivalence class contains \( k \) DAGs, this will yield \( k \) estimated total causal effects. Since we do not know which DAG is the true causal DAG, we do not know which estimated total causal effect of \( x \) on \( y \) is the correct one. Therefore, we return the entire multiset of \( k \) estimated effects (it is a multiset rather than a set because it can contain duplicate values).

One can take summary measures of the multiset. For example, the minimum absolute value provides a lower bound on the size of the true causal effect: If the minimum absolute value of all values in the multiset is larger than one, then we know that the size of the true causal effect (up to sampling error) must be larger than one.

If `method="global"`, the method as described above is carried out, where all DAGs in the equivalence class of the estimated CPDAG or PDAG `graphEst` are computed using the function `pdag2allDags`. This method is suitable for small graphs (say, up to 10 nodes).

If `method="local"`, we do not determine all DAGs in the equivalence class of the CPDAG or PDAG. Instead, we only consider some neighborhood of \( x \) in the CPDAG or PDAG.

In the case of a CPDAG, we consider all possible directions of undirected edges that have \( x \) as endpoint, such that no new v-structure is created. Maathuis, Kalisch and Buehlmann (2009) showed that there is at least one DAG in the equivalence class for each such local configuration.

In the case of a PDAG, we usually need to consider a larger neighborhood of \( x \) to determine all valid directions of undirected edges that have \( x \) as an endpoint. For details see Section 4.2 in Perkovic, Kalisch and Maathuis (2017).

Once all valid configuration in a CPDAG or PDAG are determined, we estimate the total causal effect of \( x \) on \( y \) for each valid configuration as above, using linear regression.
As a result, it follows that the multisets of total causal effects of the "global" and the "local" method have the same unique values. They may, however, have different multiplicities.

For example, a CPDAG may represent eight DAGs, and the global method may produce the multiset \{1.3, -0.5, 0.7, 1.3, 1.3, -0.5, 0.7, 0.7\}. The unique values in this set are -0.5, 0.7 and 1.3, and the multiplicities are 2, 3 and 3. The local method, on the other hand, may yield \{1.3, -0.5, -0.5, 0.7\}. The unique values are again -0.5, 0.7 and 1.3, but the multiplicities are now 2, 1 and 1. The fact that the unique values of the multisets of the "global" and "local" method are identical implies that summary measures of the multiset that only depend on the unique values (such as the minimum absolute value) can be estimate by the local method.

**Value**

A vector that represents the multiset containing the estimated possible total causal effects of \(x\) on \(y\).

**Author(s)**

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Emilija Perkovic

**References**

idaFast

Multiset of Possible Total Causal Effects for Several Target Var.s

Description

This function estimates the multiset of possible total causal effects of one variable \( x \) on a several (i.e., a vector of) target variables \( y \) from observational data. idaFast() is more efficient than looping over ida. Only method="local" (see ida) is available.

Usage

idaFast(x.pos, y.pos.set, mcov, graphEst)

Arguments

- **x.pos**: (integer) position of variable \( x \) in the covariance matrix.
- **y.pos.set**: integer vector of positions of the target variables \( y \) in the covariance matrix.
- **mcov**: covariance matrix that was used to estimate graphEst.
- **graphEst**: estimated CPDAG from the function pc. If the output of pc is pc.fit, then the estimated CPDAG can be obtained by pc.fit@graph.

Details

This function performs ida(x.pos, y.pos, mcov, graphEst, method="local", y.notparent=FALSE, verbose=FALSE) for all values of y.pos in y.pos.set simultaneously, in an efficient way. See (the help about) ida for more details. Note that the option y.notparent = TRUE is not implemented, since it is not clear how to do that efficiently without orienting all edges away from y.pos.set at the same time, which seems not to be desirable. Suggestions are welcome.

Value

Matrix with \( \text{length}(y.pos.set) \) rows. Row \( i \) contains the multiset of estimated possible total causal effects of \( x \) on \( y.pos.set[i] \). Note that all multisets in the matrix have the same length, since the parents of \( x \) are the same for all elements of \( y.pos.set \).

pc for estimating a CPDAG, and ida for estimating the multiset of possible total causal effects from observational data on only one target variable but with many more options (than here in idafast).

Examples

```r
## Simulate the true DAG
set.seed(123)
p <- 7
myDAG <- randomDAG(p, prob = 0.2) ## true DAG
myCPDAG <- dag2cpdag(myDAG) ## true CPDAG
covTrue <- trueCov(myDAG) ## true covariance matrix

## simulate data from the true DAG
n <- 10000
dat <- rmvDAG(n, myDAG)
cov.d <- cov(dat)

## estimate CPDAG (see help on the function "pc")
suffStat <- list(C = cor(dat), n = n)
pc.fit <- pc(suffStat, indepTest = gaussCItest, alpha = 0.01, p=p)

if(require(Rgraphviz)) {
  op <- par(mfrow=c(1,3))
  plot(myDAG, main="true DAG")
  plot(myCPDAG, main="true CPDAG")
  plot(pc.fit@graph, main="pc()-estimated CPDAG")
  par(op)
}

(eff.est1 <- ida(2,5, cov.d, pc.fit@graph))## method = "local" is default
(eff.est2 <- ida(2,6, cov.d, pc.fit@graph))
(eff.est3 <- ida(2,7, cov.d, pc.fit@graph))
## These three computations can be combined in an efficient way
## by using idafast :
(eff.estF <- idafast(2, c(5,6,7), cov.d, pc.fit@graph))
```

iplotPC

---

**iplotPC**

Plotting a pcAlgo object using the package igraph

---

Description

Notably, when the Rgraphviz package is not easily available, iplotPC() is an alternative for plotting a "pcAlgo" object, making use of package igraph.

It extracts the adjacency matrix and converts it into an object from package igraph which is then plotted.
Usage

iplotPC(pc.fit, labels = NULL)

Arguments

pc.fit  
an R object of class pcAlgo, as returned from skeleton() or pc().
labels  
optional labels for nodes; by default, the labels from the pc.fit object are used.

Value

Nothing. As side effect, the plot of pcAlgo object pc.fit.

Note

Note that this function does not work on fciAlgo objects, as those need different edge marks.

Author(s)

Markus Kalisch <kalisch@stat.math.ethz.ch>

See Also

showEdgeList for printing the edge list of a pcAlgo object; showamat for printing the adjacency matrix of a pcAlgo object.

Examples

## Load predefined data
data(gmg)
n <- nrow(gmg$X)
V <- colnames(gmg$X)

## define sufficient statistics
suffStat <- list(C = cor(gmg$X), n = n)
## estimate CPDAG
pc.fit <- pc(suffStat, indepTest = gaussCItest,
             alpha = 0.01, labels = V, verbose = TRUE)

## Edge list
showEdgeList(pc.fit)

## Adjacency matrix
showamat(pc.fit)

## Plot using package igraph; show estimated CPDAG:
iplotPC(pc.fit)
isValidGraph  

**Description**

Check whether the adjacency matrix amat matches the specified type.

**Usage**

```r
isValidGraph(amat, type = c("pdag", "cpdag", "dag"), verbose = FALSE)
```

**Arguments**

- `amat` : adjacency matrix of type amat.cpdag (see `amatType`)
- `type` : string specifying the type of graph of the adjacency matrix amat. It can be a DAG (type="dag"), a CPDAG (type="cpdag") or a maximally oriented PDAG (type="pdag") from Meek (1995).
- `verbose` : If TRUE, detailed output on why the graph might not be valid is provided.

**Details**

For a given adjacency matrix amat and graph type, this function checks whether the two match.

- For type = "dag" we require that amat does NOT contain directed cycles.
- For type = "cpdag" we require that amat does NOT contain directed or partially directed cycles. We also require that the undirected part of the CPDAG (represented by amat) is made up of chordal components and that our graph is maximally oriented according to rules from Meek (1995).
- For type = "pdag" we require that amat does NOT contain directed cycles. We also require that the PDAG is maximally oriented according to rules from Meek (1995). Additionally, we require that the adjacency matrix amat1 of the CPDAG corresponding to our PDAG (represented by amat), satisfies `isValidGraph(amat = amat1, type = "cpdag") == TRUE` and that there is no mismatch in the orientations implied by amat and amat1. We obtain amat1 by extracting the skeleton and v-structures from amat and then closing the orientation rules from Meek (1995).

**Value**

TRUE, if the adjacency matrix amat is of the type specified and FALSE, otherwise.

**Author(s)**

Emilija Perkovic and Markus Kalisch

isValidGraph(amat = amat, type = "pdag") ## not a valid PDAG
```

---

**jointIda**

Estimate Multiset of Possible Total Joint Effects

**Description**

`jointIda()` estimates the multiset of possible total joint effects of a set of intervention variables \(X\) on another variable \(Y\) from observational data. This is a version of `ida` that allows multiple simultaneous interventions.

**Usage**

```r
jointIda(x.pos, y.pos, mcov, graphEst = NULL, all.pasets = NULL,
          technique = c("RRC", "MCD"), type = c("pdag", "cpdag", "dag"))
```

**Arguments**

- `x.pos` (integer vector) positions of the intervention variables \(X\) in the covariance matrix.
- `y.pos` (integer) position of variable \(Y\) in the covariance matrix. \(y.pos\) can also be an integer vector, see Note.
- `mcov` (estimated) covariance matrix.
jointIda

graphEst (graphNEL object) Estimated CPDAG or PDAG. The CPDAG is typically from pc(): If the result of pc is pc.fit, the estimated CPDAG can be obtained by pc.fit@graph. The PDAG can be obtained from CPDAG by adding background knowledge using addBgKnowledge(). graphEst can only be considered if all.pasets is NULL.

all.pasets (an optional argument and the default is NULL) A list where each element is a list of size length(x.pos). Each sub-list all.pasets[[i]] contains possible parent sets of x.pos in the same order, i.e., all.pasets[[i]][[j]] is a possible parent set of x.pos[j]. This option can be used if possible parent sets of the intervention variables are known.

technique character string specifying the technique that will be used to estimate the total joint causal effects (given the parent sets), see details below.

"RRC": Recursive regressions for causal effects.

"MCD": Modifying the Cholesky decomposition.

type Type of graph "graphEst"; can be of type "cpdag", "pdag" (e.g. a CPDAG with background knowledge from Meek, 1995) or "dag".

Details

It is assumed that we have observational data that are multivariate Gaussian and faithful to the true (but unknown) underlying causal DAG (without hidden variables). Under these assumptions, this function estimates the multiset of possible total joint effects of x on y. Here the total joint effect of $X = (X_1, X_2)$ on Y is defined via Pearl’s do-calculus as the vector $\left( E[Y | do(X_1 = x_1, X_2 = x_2)] - E[Y | do(X_1 = x_1, X_2 = x_2 + 1)] , E[Y | do(X_1 = x_1, X_2 = x_2)] - E[Y | do(X_1 = x_1, X_2 = x_2 + 1)] \right)$, with a similar definition for more than two variables. These values are equal to the partial derivatives (evaluated at $(x_1, x_2)$) of $E[Y | do(X = x'_1, X_2 = x'_2)]$ with respect to $x'_1$ and $x'_2$. Moreover, under the Gaussian assumption, these partial derivatives do not depend on the values at which they are evaluated.

We estimate a multiset of possible total joint effects instead of the unique total joint effect, since it is typically impossible to identify the latter when the true underlying causal DAG is unknown (even with an infinite amount of data).

Conceptually, the method works as follows. First, we estimate the CPDAG or PDAG based on the data. The CPDAG represents the equivalence class of DAGs and can be estimated from observational data with the function pc (see the help file of this function).

The PDAG contains more orientations than the CPDAG and thus, represents a smaller equivalence class of DAGs, compared to the CPDAG. We can obtain a PDAG if we have background knowledge of, for example, certain edge orientations of undirected edges in the CPDAG. We obtain the PDAG by adding these orientations to the CPDAG using the function addBgKnowledge (see the help file of this function).

Then using the CPDAG or PDAG we extract a collection of "jointly valid" parent sets of the intervention variables from the estimated CPDAG. For each set of jointly valid parent sets we apply RRC (recursive regressions for causal effects) or MCD (modifying the Cholesky decomposition) to estimate the total joint effect of X on Y from the sample covariance matrix (see Section 3 of Nandy et. al, 2015).
Value

A matrix representing the multiset containing the estimated possible total joint effects of \( X \) on \( Y \). The number of rows is equal to \( \text{length}(x.\text{pos}) \), i.e., each column represents a vector of possible joint causal effects.

Note

For a single variable \( X \), jointIda() estimates the same quantities as ida(). If graphEst is of type = "cpdag", jointIda() obtains all.pasets by using the semi-local approach described in Section 5 in Nandy et. al, (2015). Nandy et. al, (2015) show that jointIda() yields correct multiplicities of the distinct elements of the resulting multiset (in the sense that it matches ida() with method="global" up to a constant factor).

If graphEst is of type = "pdag", jointIda() obtains all.pasets by using the semi-local approach described in Algorithm 2, Section 4.2 in Perkovic et. al (2017). For this case, jointIda() does not necessarily yield the correct multiplicities of the distinct elements of the resulting multiset (it behaves similarly to ida() with method="local").

jointIda() (like idaFast) also allows direct computation of the total joint effect of a set of intervention variables \( X \) on another set of target variables \( Y \). In this case, \( y.\text{pos} \) must be an integer vector containing positions of the target variables \( Y \) in the covariance matrix and the output is a list of matrices that correspond to the variables in \( Y \) in the same order. This method is slightly more efficient than looping over jointIda() with single target variables, if all.pasets is not specified.

jointIda(x.pos=c(1,2), y.pos=6, covTrue, graphEst=myPDAG, technique="MCD", type = "pdag")

## Instead of knowing the true CPDAG or PDAG, it is enough to know only
## the jointly valid parent sets of the intervention variables
## to use RRC or MCD
## all.jointly.valid.pasets:
ajv.pasets <- list(list(1:5, c(3,4)), list(integer(0), c(3,4)), list(3, c(3,4)))
jointIda(x.pos=c(1,2), y.pos=6, covTrue, all.pasets=ajv.pasets, technique="RRC")
jointIda(x.pos=c(1,2), y.pos=6, covTrue, all.pasets=ajv.pasets, technique="MCD")

## From the true DAG, we can compute the true total joint effects
## using RRC or MCD
cat("dim covTrue: ", dim(covTrue), "\n")
jointIda(x.pos=c(1,2), y.pos=6, covTrue, graphEst=myDAG, technique="RRC", type = "dag")
jointIda(x.pos=c(1,2), y.pos=6, covTrue, graphEst=myDAG, technique="MCD", type = "dag")

## When working with data, we have to use the estimated CPDAG or PDAG
## and the sample covariance matrix
jointIda(x.pos=c(1,2), y.pos=6, cov(dat), graphEst=p.c.fit@graph, technique="RRC", type = "cpdag")
jointIda(x.pos=c(1,2), y.pos=6, cov(dat), graphEst=p.c.fit@graph, technique="MCD", type = "cpdag")
jointIda(x.pos=c(1,2), y.pos=6, cov(dat), graphEst=pc.fit.pdag, technique="RRC", type = "pdag")
jointIda(x.pos=c(1,2), y.pos=6, cov(dat), graphEst=pc.fit.pdag, technique="MCD", type = "pdag")
## RRC and MCD can produce different results when working with data

## jointIda also works when x.pos has length 1 and in the following example
## it gives the same result as ida() (see Note)
##
## When the CPDAG is known
jointIda(x.pos=1, y.pos=6, covTrue, graphEst=myCPDAG, technique="RRC", type = "cpdag")
ida(x.pos=1, y.pos=6, covTrue, graphEst=myCPDAG, method="global", type = "cpdag")

## When the PDAG is known
jointIda(x.pos=1, y.pos=6, covTrue, graphEst=myPDAG, technique="RRC", type = "pdag")
ida(x.pos=1, y.pos=6, covTrue, graphEst=myPDAG, method="global", type = "pdag")

## When the DAG is known
jointIda(x.pos=1, y.pos=6, covTrue, graphEst=myDAG, technique="RRC", type = "dag")
ida(x.pos=1, y.pos=6, covTrue, graphEst=myDAG, method="global")
## Note that, causalEffect(myDAG,y=6,x=1) does not give the correct value in this case,
## since this function requires that the variables are in a causal order.

---

**legal.path**

*Check if a 3-node-path is Legal*

**Description**

Check if the path $a \rightarrow b \rightarrow c$ is legal.

A 3-node path $a \rightarrow b \rightarrow c$ is “legal” iff either $b$ is a collider or $a \rightarrow b \rightarrow c$ is a triangle.

**Usage**

`legal.path(a, b, c, amat)`

**Arguments**

- `a,b,c` (integer) positions in adjacency matrix of nodes $a$, $b$, and $c$, respectively.
- `amat` Adjacency matrix (coding 0,1,2,3 for no edge, circle, arrowhead, tail; e.g., `amat[a,b] = 2` and `amat[b,a] = 3` implies $a \rightarrow b$)

**Value**

`TRUE` if path is legal, otherwise `FALSE`.

**Note**

Prerequisite: $a \rightarrow b \rightarrow c$ *must* be in a path (and this is *not* checked by `legal.path()`).
**Author(s)**

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

**Examples**

```r
amat <- matrix( c(0,1,1,0, 2,0,1,0,0, 2,2,0,2,1,
                      0,0,1,0,0, 0,0,2,0,0), 5,5)
legal.path(1,3,5, amat)
legal.path(1,2,3, amat)
legal.path(2,3,4, amat)
```

**Description**

Fits a Linear non-Gaussian Acyclic Model (LiNGAM) to the data and returns the corresponding DAG.

For details, see the reference below.

**Usage**

```r
lingam(xL, verbose = FALSE)
```

## For back-compatibility; this is *deprecated*

LINGAM(xL, verbose = FALSE)

**Arguments**

`x`  
n x p data matrix (n: sample size, p: number of variables).

`verbose`  
logical or integer indicating that increased diagnostic output is to be provided.

**Value**

`lingam()` returns an `R` object of (S3) class "LINGAM", basically a `list` with components

- `Bpruned`  
a $p \times p$ matrix $B$ of linear coefficients, where $B_{i,j}$ corresponds to a directed edge from $j$ to $i$.

- `stde`  
a vector of length $p$ with the standard deviations of the estimated residuals

- `ci`  
a vector of length $p$ with the intercepts of each equation

`LINGAM()` — *deprecated now* — returns a `list` with components

- `Adj`  
a $p \times p$ 0/1 adjacency matrix $A$. $A[i,j] == 1$ corresponds to a directed edge from $i$ to $j$.

- `B`  
$p \times p$ matrix of corresponding linear coefficients. Note it corresponds to the *transpose* of Adj, i.e., identical( Adj, t(B) != 0 ) is true.

cat("estimated noise standard deviations:
"
show(res$stde)
```
mat2targets

Conversion between an intervention matrix and a list of intervention targets

Description

In a data set with \( n \) measurements of \( p \) variables, intervened variables can be specified in two ways:

- with a **logical** intervention matrix of dimension \( n \times p \), where the entry \([i, j]\) indicates whether variable \( j \) has been intervened in measurement \( i \); or
- with a list of (unique) intervention targets and a \( p \)-dimensional vector indicating the indices of the intervention targets of the \( p \) measurements.
The function `mat2targets` converts the first representation to the second one, the function `targets2mat` does the reverse conversion. The second representation can be used to create scoring objects (see `score`) and to run causal inference methods based on interventional data such as `gies` or `simy`.

Usage

```r
mat2targets(A) targets2mat(p, targets, target.index)
```

Arguments

- **A**: Logical matrix with \( n \) rows and \( p \) columns, where \( n \) is the sample size of a data set with jointly interventional and observational data, and \( p \) is the number of variables. \( A[i, j] \) is TRUE iff variable \( j \) is intervened in data point \( i \).
- **p**: Number of variables
- **targets**: List of unique intervention targets
- **target.index**: Vector of intervention target indices. The intervention target of data point \( i \) is encoded as `targets[[target.index[i]]].`

Value

`mat2targets` returns a list with two components:

- **targets**: A list of unique intervention targets.
- **target.index**: A vector of intervention target indices. The intervention target of data point \( i \) is encoded as `targets[[target.index[i]]].`

Author(s)

Alain Hauser (<alain.hauser@bfh.ch>)

`score, gies, simy`

Examples

```r
## Specify interventions using a matrix
p <- 5
n <- 10
A <- matrix(FALSE, nrow = n, ncol = p)
for (i in 1:n) A[i, (i-1) %% p + 1] <- TRUE

## Generate list of intervention targets and corresponding indices
target.list <- mat2targets(A)

for (i in 1:length(target.list$target.index))
  sprintf("Intervention target of %d-th data point: %d", i, target.list$targets[[target.list$target.index[i]]])
```
Compute (Large) Correlation Matrix

Description
Compute a correlation matrix, possibly by robust methods, applicable also for the case of a large number of variables.

Usage
```r
mcor(dm, method = c("standard", "Qn", "QnStable", "ogkScaleTau2", "ogkQn", "shrink"))
```

Arguments
- `dm` numeric data matrix; rows are observations ("samples"), columns are variables.
- `method` a string: "standard" (default), "Qn", "QnStable", "ogkQn" and "shrink" en- vokes standard, elementwise robust (based on $Q_n$ scale estimator, see `Qn`), robust ($Q_n$ using OGK, see `covOGK`) or shrunked correlation estimate respectively.

Details
The "standard" method envoke a standard correlation estimator. "Qn" envoke a robust, elementwise correlation estimator based on the $Q_n$ scale estimator. "QnStable" also uses the $Q_n$ scale estimator, but uses an improved way of transforming that into the correlation estimator. "ogkQn" envoke a correlation estimator based on $Q_n$ using OGK. "shrink" is only useful when used with `pcSelect`. An optimal shrinkage parameter is used. Only correlation between response and covariates is shrunked.

Value
A correlation matrix estimated by the specified method.

Author(s)
Markus Kalisch <kalisch@stat.math.ethz.ch> and Martin Maechler

`Qn` and `covOGK` from package `robustbase`. `pcorOrder` for computing partial correlations.
Examples

```r
## produce uncorrelated normal random variables
set.seed(42)
x <- rnorm(100)
y <- 2*x + rnorm(100)
## compute correlation of var1 and var2
mcor(cbind(x, y), method="standard")
```

```r
## repeat but this time with heavy-tailed noise
ynoise <- 2*x + rcauchy(100)
mcor(cbind(x, ynoise), method="standard") ## shows almost no correlation
mcor(cbind(x, ynoise), method="Qn") ## shows a lot correlation
mcor(cbind(x, ynoise), method="QnStable") ## shows still much correlation
mcor(cbind(x, ynoise), method="ogkQn") ## ditto
```

pag2mag

Transform a PAG into a MAG in the Corresponding Markov Equivalence Class

Description

Transform a Partial Ancestral Graph (PAG) into a valid Maximal Ancestral Graph (MAG) that belongs to the Markov equivalence class represented by the given PAG, with no additional edges into node x.

Usage

```r
pag2mag(amat.pag, x, max.chordal = 10, verbose = FALSE)
```

Arguments

- **amat.pag**: Adjacency matrix of type `amat.pag`
- **x**: Position in adjacency matrix of node in the PAG into which no additional edges are oriented.
- **max.chordal**: Positive integer: graph paths larger than `max.chordal` are considered to be too large to be checked for chordality.
- **verbose**: Logical; if true, some output is produced during computation.

Details

This function converts a PAG (adjacency matrix) to a valid MAG (adjacency matrix) that belongs to the Markov equivalence class represented by the given PAG. Note that we assume that there are no selection variables, meaning that the edges in the PAG can be of the following types: ->, <->, o->, and o-o. In a first step, it uses the Arrowhead Augmentation of Zhang (2006), i.e., any o-> edge is oriented into ->. Afterwards, it orients each chordal component into a valid DAG without orienting any additional edges into x.

This function is used in the Generalized Backdoor Criterion `backdoor` with type=“pag”, see Maathuis and Colombo (2015) for details.
Value

The output is an adjacency matrix of type amat.pag representing a valid MAG that belongs to the Markov equivalence class represented by the given PAG.

Author(s)

Diego Colombo, Markus Kalisch and Martin Maechler.

Examples

```r
## create the graph
set.seed(78)
p <- 12
g <- randomDAG(p, prob = 0.4)
## Compute the true covariance and then correlation matrix of g:
true.corr <- cov2cor(trueCov(g))

## define nodes 2 and 6 to be latent variables
L <- c(2,6)

## Find PAG
## As dependence "oracle", we use the true correlation matrix in
## gaussCITest() with a large "virtual sample size" and a large alpha:
true.pag <- dag2pag(suffStat = list(C= true.corr, n= 10^9),
indepTest= gaussCITest, graph=g, L=L, alpha= 0.9999)

## find a valid MAG such that no additional edges are directed into
(amat.mag <- pag2magAM(true.pag@amat, 4)) # -> the adj.matrix of the MAG
```

---

ParDAG-class  

**Class** "ParDAG" of Parametric Causal Models

Description

This virtual base class represents a parametric causal model.
Details

The class "ParDAG" serves as a basis for simulating observational and/or interventional data from causal models as well as for parameter estimation (maximum-likelihood estimation) for a given causal model in the presence of a data set with jointly observational and interventional data.

The virtual base class "ParDAG" provides a "skeleton" for all functions relied to the aforementioned task. In practical cases, a user may always choose an appropriate class derived from ParDAG which represents a specific parametric model class. The base class itself does not represent such a model class.

Constructor

```
new("ParDAG", nodes, in.edges, params)
```

*nodes* Vector of node names; cf. also field .nodes.

*in.edges* A list of length p consisting of index vectors indicating the edges pointing into the nodes of the DAG.

*params* A list of length p consisting of parameter vectors modeling the conditional distribution of a node given its parents; cf. also field .params.

Fields

* .nodes: Vector of node names; defaults to as.character(1:p), where p denotes the number of nodes (variables) of the model.

* .in.edges: A list of length p consisting of index vectors indicating the edges pointing into the nodes of the DAG.

* .params: A list of length p consisting of parameter vectors modeling the conditional distribution of a node given its parents. The entries of the parameter vectors only get a concrete meaning in derived classes belonging to specific parametric model classes.

Class-Based Methods

- `node.count()`: Yields the number of nodes (variables) of the model.
- `simulate(n, target, int.level)`: Generates n (observational or interventional) samples from the parametric causal model. The intervention target to be used is specified by the parameter *target*; if the target is empty (*target = integer(0)*), observational samples are generated. *int.level* indicates the values of the intervened variables; if it is a vector of the same length as *target*, all samples are drawn from the same intervention levels; if it is a matrix with *n* rows and as many columns as *target* has entries, its rows are interpreted as individual intervention levels for each sample.
- `edge.count()`: Yields the number of edges (arrows) in the DAG.
- `mle.fit(score)`: Fits the parameters using an appropriate *Score* object.

Methods

- `plot signature(x = "ParDAG", y = "ANY")`: plots the underlying DAG of the causal model. Parameters are not visualized.
**pc**

*Estimate the Equivalence Class of a DAG using the PC Algorithm*

**Description**

Estimate the equivalence class of a directed acyclic graph (DAG) from observational data, using the PC-algorithm.

**Usage**

```r
pc(suffstat, indepTest, alpha, labels, p,
   fixedGaps = NULL, fixedEdges = NULL, NAdelete = TRUE, m.max = Inf,
   u2pd = c("relaxed", "rand", "retry"),
   skel.method = c("stable", "original", "stable.fast"),
   conservative = FALSE, maj.rule = FALSE, solve.confl = FALSE,
   numCores = 1, verbose = FALSE)
```

**Arguments**

- **suffStat**: A list of sufficient statistics, containing all necessary elements for the conditional independence decisions in the function `indepTest`.
- **indepTest**: A function for testing conditional independence. It is internally called as `indepTest(x,y,S,suffStat)`, and tests conditional independence of x and y given S. Here, x and y are variables, and S is a (possibly empty) vector of variables (all variables are denoted by their (integer) column positions in the adjacency matrix). suffStat is a list, see the argument above. The return value of indepTest is the p-value of the test for conditional independence.
- **alpha**: significance level (number in (0, 1) for the individual conditional independence tests.
- **labels**: (optional) character vector of variable (or “node”) names. Typically preferred to specifying p.
- **p**: (optional) number of variables (or nodes). May be specified if labels are not, in which case labels is set to 1:p.
- **numCores**: Specifies the number of cores to be used for parallel estimation of skeleton.
- **verbose**: If TRUE, detailed output is provided.
- **fixedGaps**: A logical matrix of dimension p*p. If entry [i,j] or [j,i] (or both) are TRUE, the edge i-j is removed before starting the algorithm. Therefore, this edge is guaranteed to be absent in the resulting graph.
fixedEdges A logical matrix of dimension p*p. If entry [i,j] or [j,i] (or both) are TRUE, the edge i-j is never considered for removal. Therefore, this edge is guaranteed to be present in the resulting graph.

NAdelete If indepTest returns NA and this option is TRUE, the corresponding edge is deleted. If this option is FALSE, the edge is not deleted.

m.max Maximal size of the conditioning sets that are considered in the conditional independence tests.

u2pd String specifying the method for dealing with conflicting information when trying to orient edges (see details below).

skel.method Character string specifying method; the default, "stable" provides an order-independent skeleton, see skeleton.

conservative Logical indicating if the conservative PC is used. In this case, only option u2pd = "relaxed" is supported. Note that therefore the resulting object might not be extendable to a DAG. See details for more information.

maj.rule Logical indicating that the triples shall be checked for ambiguity using a majority rule idea, which is less strict than the conservative PC algorithm. For more information, see details.

solve.conf1 If TRUE, the orientation of the v-structures and the orientation rules work with lists for candidate sets and allow bi-directed edges to resolve conflicting edge orientations. In this case, only option u2pd = relaxed is supported. Note that therefore the resulting object might not be a CPDAG because bi-directed edges might be present. See details for more information.

Details

Under the assumption that the distribution of the observed variables is faithful to a DAG, this function estimates the Markov equivalence class of the DAG. We do not estimate the DAG itself, because this is typically impossible (even with an infinite amount of data), since different DAGs can describe the same conditional independence relationships. Since all DAGs in an equivalence class describe the same conditional independence relationships, they are equally valid ways to describe the conditional dependence structure that was given as input.

All DAGs in a Markov equivalence class have the same skeleton (i.e., the same adjacency information) and the same v-structures (see definition below). However, the direction of some edges may be undetermined, in the sense that they point one way in one DAG in the equivalence class, while they point the other way in another DAG in the equivalence class.

A Markov equivalence class can be uniquely represented by a completed partially directed acyclic graph (CPDAG). A CPDAG contains undirected and directed edges. The edges have the following interpretation: (i) there is a (directed or undirected) edge between i and j if and only if variables i and j are conditionally dependent given S for all possible subsets S of the remaining nodes; (ii) a directed edge $i \rightarrow j$ means that this directed edge is present in all DAGs in the Markov equivalence class; (iii) an undirected edge $i \perp j$ means that there is at least one DAG in the Markov equivalence class with edge $i \rightarrow j$ and there is at least one DAG in the Markov equivalence class with edge $i \leftarrow j$.

The CPDAG is estimated using the PC algorithm (named after its inventors Peter Spirtes and Clark Glymour). The skeleton is estimated by the function skeleton which uses a modified version of the original PC algorithm (see Colombo and Maathuis (2014) for details). The original PC algorithm
is known to be order-dependent, in the sense that the output depends on the order in which the variables are given. Therefore, Colombo and Maathuis (2014) proposed a simple modification, called PC-stable, that yields order-independent adjacencies in the skeleton (see the help file of this function for details). Subsequently, as many edges as possible are oriented. This is done in two steps. It is important to note that if no further actions are taken (see below) these two steps still remain order-dependent.

The edges are oriented as follows. First, the algorithm considers all triples \((a, b, c)\), where \(a\) and \(b\) are adjacent, \(b\) and \(c\) are adjacent, but \(a\) and \(c\) are not adjacent. For all such triples, we direct both edges towards \(b\) \((a \rightarrow b \leftarrow c)\) if and only if \(b\) was not part of the conditioning set that made the edge between \(a\) and \(c\) drop out. These conditioning sets were saved in \(\text{sepset}\). The structure \(a \rightarrow b \leftarrow c\) is called a v-structure.

After determining all v-structures, there may still be undirected edges. It may be possible to direct some of these edges, since one can deduce that one of the two possible directions of the edge is invalid because it introduces a new v-structure or a directed cycle. Such edges are found by repeatedly applying rules R1-R3 of the PC algorithm as given in Algorithm 2 of Kalisch and Bühlmann (2007). The algorithm stops if none of the rules is applicable to the graph.

The conservative PC algorithm (\texttt{conservative = TRUE}) is a slight variation of the PC algorithm (see Ramsey et al. 2006). After the skeleton is computed, all potential v-structures \(a \rightarrow b \leftarrow c\) are checked in the following way. We test whether \(a\) and \(c\) are independent conditioning on all subsets of the neighbors of \(a\) and all subsets of the neighbors of \(c\). When a subset makes \(a\) and \(c\) conditionally independent, we call it a separating set. If \(b\) is in no such separating set or in all such separating sets, no further action is taken and the usual PC is continued. If, however, \(b\) is in only some separating sets, the triple \(a \rightarrow b \leftarrow c\) is marked as 'ambiguous'. Moreover, if no separating set is found among the neighbors, the triple is also marked as 'ambiguous'. An ambiguous triple is not oriented as a v-structure. Furthermore, no further orientation rule that needs to know whether \(a \rightarrow b \leftarrow c\) is a v-structure or not is applied. Instead of using the conservative version, which is quite strict towards the v-structures, Colombo and Maathuis (2014) introduced a less strict version for the v-structures called majority rule. This adaptation can be called using \texttt{maj.rule = TRUE}. In this case, the triple \(a \rightarrow b \leftarrow c\) is marked as 'ambiguous' if and only if \(b\) is in exactly 50 percent of such separating sets or no separating set was found. If \(b\) is in less than 50 percent of the separating sets it is set as a v-structure, and if in more than 50 percent it is set as a non v-structure (for more details see Colombo and Maathuis, 2014). The usage of both the conservative and the majority rule versions resolve the order-dependence issues of the determination of the v-structures.

Sampling errors (or hidden variables) can lead to conflicting information about edge directions. For example, one may find that \(a \rightarrow b \leftarrow c\) and \(b \leftarrow c \rightarrow d\) should both be directed as v-structures. This gives conflicting information about the edge \(b \leftarrow c\), since it should be directed as \(b \leftarrow c\) in v-structure \(a \rightarrow b \leftarrow c\), while it should be directed as \(b \rightarrow c\) in v-structure \(b \rightarrow c \leftarrow d\). With the option \texttt{solve.conf1 = FALSE}, in such cases, we simply overwrite the directions of the conflicting edge. In the example above this means that we obtain \(a \rightarrow b \rightarrow c \leftarrow d\) if \(a \rightarrow b \leftarrow c\) was visited first, and \(a \rightarrow b \leftarrow c \leftarrow d\) if \(b \leftarrow c \rightarrow d\) was visited first, meaning that the final orientation on the edge depends on the ordering in which the v-structures were considered. With the option \texttt{solve.conf1 = TRUE} (which is only supported with option \texttt{u2pd = "relaxed"}), we first generate a list of all (unambiguous) v-structures (in the example above \(a \rightarrow b \leftarrow c\) and \(b \leftarrow c \rightarrow d\)), and then we simply orient them allowing both directions on the edge \(b \leftarrow c\), namely we allow the bi-directed edge \(b \leftrightarrow c\) resolving the order-dependence issues on the edge orientations. We denote bi-directed edges in the adjacency matrix \(M\) of the graph as \(M[b,c] = 2\) and \(M[c,b] = 2\). In a similar way, using lists for the candidate edges for each orientation rule and allowing bi-directed edges, the
order-dependence issues in the orientation rules can be resolved. Note that bi-directed edges merely represent a conflicting orientation and they should not to be interpreted causally. The usage of these lists for the candidate edges and allowing bi-directed edges resolves the order-dependence issues on the orientation of the v-structures and on the orientation rules, see Colombo and Maathuis (2014) for more details.

Note that calling (conservative = TRUE), or maj.rule = TRUE, together with solve.conf1 = TRUE produces a fully order-independent output, see Colombo and Maathuis (2014).

Sampling errors, non faithfulness, or hidden variables can also lead to non-extendable CPDAGs, meaning that there does not exist a DAG that has the same skeleton and v-structures as the graph found by the algorithm. An example of this is an undirected cycle consisting of the edges $a \rightarrow b \rightarrow c \rightarrow d$ and $d \rightarrow a$. In this case it is impossible to direct the edges without creating a cycle or a new v-structure. The option u2pd specifies what should be done in such a situation. If the option is set to "relaxed", the algorithm simply outputs the invalid CPDAG. If the option is set to "rand", all direction information is discarded and a random DAG is generated on the skeleton, which is then converted into its CPDAG. If the option is set to "retry", up to 100 combinations of possible directions of the ambiguous edges are tried, and the first combination that results in an extendable CPDAG is chosen. If no valid combination is found, an arbitrary DAG is generated on the skeleton as in the option "rand", and then converted into its CPDAG. Note that the output can also be an invalid CPDAG, in the sense that it cannot arise from the oracle PC algorithm, but be extendible to a DAG, for example $a \rightarrow b \leftarrow c \leftarrow d$. In this case, u2pd is not used.

Using the function isValidGraph one can check if the final output is indeed a valid CPDAG.

Notes: (1) Throughout, the algorithm works with the column positions of the variables in the adjacency matrix, and not with the names of the variables. (2) When plotting the object, undirected and bidirected edges are equivalent.

Value

An object of class "pcAlgo" (see pcAlgo) containing an estimate of the equivalence class of the underlying DAG.

Utility for conservative and majority rule in PC and FCI

Description

The pc.cons.intern() function is used in pc and fci, notably when conservative = TRUE (conservative orientation of v-structures) or maj.rule = TRUE (majority rule orientation of v-structures).

Usage

pc.cons.intern(sk, suffstat, indepTest, alpha, version.unf = c(NA, NA),
        maj.rule = FALSE, verbose = FALSE)

Arguments

- **sk**: A skeleton object as returned from skeleton().
- **suffstat**: Sufficient statistic: List containing all necessary elements for the conditional independence decisions in the function indepTest.
- **indepTest**: Pre-defined function for testing conditional independence. The function is internally called as indepTest(x,y,s,suffStat), and tests conditional independence of x and y given s. Here, x and y are variables, and s is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). suffStat is a list containing all relevant elements for the conditional independence decisions. The return value of indepTest is the p-value of the test for conditional independence.
- **alpha**: Significance level for the individual conditional independence tests.
- **version.unf**: Vector of length two. If version.unf[2]==1, the initial separating set found by the PC/FCI algorithm is added to the set of separating sets; if version.unf[2]==2, it is not added. In the latter case, if the set of separating sets is empty, the triple is marked as unambiguous if version.unf[1]==1, and as ambiguous if version.unf[1]==2.
- **maj.rule**: Logical indicating if the triples are checked for ambiguity using the majority rule idea, which is less strict than the standard conservative method.
- **verbose**: Logical asking for detailed output.

Details

For any unshielded triple A-B-C, consider all subsets of the neighbors of A and of the neighbors of C, and record all such sets D for which A and C are conditionally independent given D. We call such sets “separating sets”.

If version.unf[2]==1, the initial separating set found in the PC/FCI algorithm is added to this set of separating sets. If version.unf[2]==2, the initial separating set is not added (as in Tetrad).
In the latter case, if the set of separating sets is empty, then the triple is marked as 'ambiguous' if version.unf[1]==2, for example in `pc`, or as 'unambiguous' if version.unf[1]==1, for example in `fci`. Otherwise, there is at least one separating set. If maj.rule=FALSE, the conservative PC algorithm is used (Ramsey et al., 2006): If B is in some but not all separating sets, the triple is marked as ambiguous. Otherwise it is treated as in the standard PC algorithm. If maj.rule=TRUE, the majority rule is applied (Colombo and Maathuis, 2014): The triple is marked as 'ambiguous' if B is in exactly 50 percent of the separating sets. If it is in less than 50 percent it is marked as a v-structure, and if it is in more than 50 percent it is marked as a non v-structure.

Note: This function modifies the separating sets for unambiguous triples in the skeleton object (adding or removing B) to ensure that the usual orientations rules later on lead to the correct v-structures/non v-structures.

Value

- `unfTripl` numeric vector of triples coded as numbers (via `triple2numb()`) that were marked as ambiguous.
- `vers` Vector containing the version (1 or 2) of the corresponding triple saved in `unfTripl` (1=normal ambiguous triple, i.e., B is in some sepsets but not all or none; 2=triple coming from version.unf[1]==2, i.e., a and c are indep given the initial sepset but there does not exist a subset of the neighbours of a or of c that d-separates them.)
- `sk` The updated skeleton-object (separating sets might have been updated).

`skeleton`, `pc`, `fci`

Transform the adjacency matrix from `pcalg` into a `dagitty` object.

Description

Transform the adjacency matrix of type amat.cpdag or amat.pag (for details on coding see `amatType`).
Usage

pcalg2dagitty(amat, labels, type = "cpdag")

Arguments

amat            adjacency matrix of type amat.cpdag or amat.pag
labels          character vector of variable (or “node”) names.
type            string specifying the type of graph of the adjacency matrix amat. It can be a DAG (type="dag"), a CPDAG (type="cpdag") or a maximally oriented PDAG (type="pdag") from Meek (1995); then the type of adjacency matrix is assumed to be amat.cpdag. It can also be a MAG (type = "mag") or a PAG (type="pag"); then the type of the adjacency matrix is assumed to be amat.pag.

Details

For a given adjacency matrix amat the form amat.cpdag or amat.pag and a specified graph type, this function returns a dagitty object corresponding to the graph structure specified by amat, labels and type. The resulting object is compatible with the dagitty package.

Value

A dagitty graph (see the dagitty package).

Author(s)

Emilija Perkovic and Markus Kalisch

Examples

data(gmG)
n <- nrow (gmG$X)
V <- colnames(gmG$X) # labels aka node names

amat <- wgtMatrix(gmG$g)
amat[amat != 0] <- 1
dagitty_dag1 <- pcalg2dagitty(amat,V,type="dag")

Description

This function is DEPRECATED! Use skeleton, pc or fci instead.

Use the PC-algorithm to estimate the underlying graph ("skeleton") or the equivalence class (CPDAG) of a DAG.
Usage

pcAlgo(dm = NA, C = NA, n=NA, alpha, corMethod = "standard",
verbose=FALSE, directed=FALSE, G=NULL, datatype = "continuous",
NAdelete=TRUE, m.max=Inf, u2pd = "rand", psepset=FALSE)

Arguments

dm               Data matrix; rows correspond to samples, cols correspond to nodes.
C               Correlation matrix; this is an alternative for specifying the data matrix.
n               Sample size; this is only needed if the data matrix is not provided.
alpha            Significance level for the individual partial correlation tests.
corMethod       A character string specifying the method for (partial) correlation estimation.
                 "standard", "QnStable", "Qn" or "ogkQn" for standard and robust (based on the
                 Qn scale estimator without and with OGK) correlation estimation. For robust
                 estimation, we recommend "QnStable".
verbose          0-no output, 1-small output, 2-details; using 1 and 2 makes the function very
                 much slower
directed         If FALSE, the underlying skeleton is computed; if TRUE, the underlying CPDAG
                 is computed
G               The adjacency matrix of the graph from which the algorithm should start (logi-
                 cal)
datatype         Distinguish between discrete and continuous data
NAdelete         Delete edge if pval=NA (for discrete data)
m.max            Maximal size of conditioning set
u2pd             Function used for converting skeleton to cpdag. "rand" (use udag2pdag); "re-
                 laxed" (use udag2pdagRelaxed); "retry" (use udag2pdagSpecial)
psepset          If true, also possible separation sets are tested.

Value

An object of class "pcAlgo" (see pcAlgo) containing an undirected graph (object of class "graph",
see graph-class from the package graph) (without weights) as estimate of the skeleton or the
CPDAG of the underlying DAG.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler.

References

MIT Press.
Class "pcAlgo" of PC Algorithm Results, incl. Skeleton

Description

This class of objects is returned by the functions skeleton and pc to represent the (skeleton) of an estimated CPDAG. Objects of this class have methods for the functions plot, show and summary.

Usage

```r
## S4 method for signature 'pcAlgo,ANY'
plot(x, y, main = NULL,
     zvalue.lwd = FALSE, lwd.max = 7, labels = NULL, ...)
## S3 method for class 'pcAlgo'
print(x, amat = FALSE, zero.print = ".", ...)
## S4 method for signature 'pcAlgo'
summary(object, amat = TRUE, zero.print = ".", ...)
## S4 method for signature 'pcAlgo'
show(object)
```

Arguments

- **x**, object a "pcAlgo" object.
- **y** (generic plot() argument; unused).
- **main** main title for the plot (with an automatic default).
- **zvalue.lwd** logical indicating if the line width (lwd) of the edges should be made proportional to the entries of matrix zMin (originally) or derived from matrix pMax.
- **lwd.max** maximal lwd to be used, if zvalue.lwd is true.
- **labels** if non-NULL, these are used to define node attributes nodeAttrs and attrs, passed to agopen() from package Rgraphviz.
- **amat** logical indicating if the adjacency matrix should be shown (printed) as well.
- **zero.print** string for printing 0 ('zero') entries in the adjacency matrix.
- **...** optional further arguments (passed from and to methods).

Creation of objects

Objects are typically created as result from skeleton() or pc(), but could be be created by calls of the form new("pcAlgo", ...).
Slots

The slots call, n, max.ord, n.edgetests, sepset, and pMax are inherited from class "gAlgo", see there.

In addition, "pcAlgo" has slots

- `graph`: Object of class "graph": the undirected or partially directed graph that was estimated.
- `zMin`: Deprecated.

Extends

Class "gAlgo".

Methods

- `plot` signature(x = "pcAlgo"): Plot the resulting graph. If argument "zvalue.lwd" is true, the linewidth an edge reflects zMin, so that thicker lines indicate more reliable dependencies. The argument "lwd.max" controls the maximum linewidth.
- `show` signature(object = "pcAlgo"): Show basic properties of the fitted object
- `summary` signature(object = "pcAlgo"): Show details of the fitted object

Examples

```r
showClass("pcAlgo")

## generate a pcAlgo object
p <- 8
set.seed(45)
myDAG <- randomDAG(p, prob = 0.3)
n <- 10000
d.mat <- rmVDAG(n, myDAG, errDist = "normal")
suffStat <- list(C = cor(d.mat), n = n)
pc.fit <- pc(suffStat, indepTest = gaussCItest, alpha = 0.01, p = p)

## use methods of class pcAlgo
show(pc.fit)
if(require(Rgraphviz))
  plot(pc.fit)
summary(pc.fit)

## access slots of this object
(g <- pc.fit@graph)
str(ss <- pc.fit@sepset, max=1)
```
pcorOrder  

**Compute Partial Correlations**

**Description**

This function computes partial correlations given a correlation matrix using a recursive algorithm.

**Usage**

```r
pcorOrder(i, j, k, C, cut.at = 0.9999999)
```

**Arguments**

- `i, j` (integer) position of variable `i` and `j`, respectively, in correlation matrix.
- `k` (integer) positions of zero or more conditioning variables in the correlation matrix.
- `C` Correlation matrix (matrix)
- `cut.at` Number slightly smaller than one; if `c` is `cut.at`, values outside of `[-c, c]` are set to `-c` or `c` respectively.

**Details**

The partial correlations are computed using a recursive formula if the size of the conditioning set is one. For larger conditioning sets, the pseudoinverse of parts of the correlation matrix is computed (by `pseudoinverse()` from package `corpcor`). The pseudoinverse instead of the inverse is used in order to avoid numerical problems.

**Value**

The partial correlation of `i` and `j` given the set `k`.

**Author(s)**

Markus Kalisch `<kalisch@stat.math.ethz.ch>` and Martin Maechler

**See Also**

`condIndFisherZ` for testing zero partial correlation.

**Examples**

```r
## produce uncorrelated normal random variables
mat <- matrix(rnorm(3*20), 20, 3)
## compute partial correlation of var1 and var2 given var3
pcorOrder(1, 2, 3, cor(mat))

## define graphical model, simulate data and compute
## partial correlation with bigger conditional set
```
**pcSelect**

*PC-Select: Estimate subgraph around a response variable*

**Description**

The goal is feature selection: If you have a response variable $y$ and a data matrix $dm$, we want to know which variables are “strongly influential” on $y$. The type of influence is the same as in the PC-Algorithm, i.e., $y$ and $x$ (a column of $dm$) are associated if they are correlated even when conditioning on any subset of the remaining columns in $dm$. Therefore, only very strong relations will be found and the result is typically a subset of other feature selection techniques. Note that there are also robust correlation methods available which render this method robust.

**Usage**

```r
pcSelect(y, dm, alpha, corMethod = "standard",
         verbose = FALSE, directed = FALSE)
```

**Arguments**

- **y**  
  response vector.

- **dm**  
  data matrix (rows: samples/observations, columns: variables); `nrow(dm) == length(y)`.

- **alpha**  
  significance level of individual partial correlation tests.

- **corMethod**  
  a string determining the method for correlation estimation via `mcor()`; specifically any of the `mcor(*, method = ".")` can be used, e.g., "Qn" for one kind of robust correlation estimate.

- **verbose**  
  logical or in `\{0, 1, 2\}`;  
  \[\text{FALSE, 0}: \text{No output,} \]
  \[\text{TRUE, 1}: \text{Little output,} \]
  \[\text{2}: \text{Detailed output.} \]

  Note that such diagnostic output may make the function considerably slower.

- **directed**  
  logical; should the output graph be directed?

**Details**

This function basically applies `pc` on the data matrix obtained by joining $y$ and $dm$. Since the output is not concerned with the edges found within the columns of $dm$, the algorithm is adapted accordingly. Therefore, the runtime and the ability to deal with large datasets is typically increased substantially.
Value

G  A logical vector indicating which column of dm is associated with y.

zMin  The minimal z-values when testing partial correlations between y and each column of dm. The larger the number, the more consistent is the edge with the data.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler.

References

See Also

pc which is the more general version of this function; `pcSelect.preSel` which applies `pcSelect()` twice.

Examples

```r
p <- 10
## generate and draw random DAG :
suppressWarnings(RNGversion("3.5.0"))
set.seed(101)
myDAG <- randomDAG(p, prob = 0.2)
if (require(Rgraphviz)) {
  plot(myDAG, main = "randomDAG(10, prob = 0.2")
}
## generate 1000 samples of DAG using standard normal error distribution
n <- 1000
d.mat <- rmvDAG(n, myDAG, errDist = "normal")

## let's pretend that the 10th column is the response and the first 9
## columns are explanatory variable. Which of the first 9 variables
## "cause" the tenth variable?
y <- d.mat[,10]
dm <- d.mat[,,-10]
(pcS <- pcSelect(d.mat[,10], d.mat[,,-10], alpha=0.05))
## You see, that variable 4,5,6 are considered as important
## By inspecting zMin,
with(pcS, zMin[G])
## you can also see that the influence of variable 6
## is most evident from the data (its zMin is 18.64, so quite large - as
## a rule of thumb for judging what is large, you could use quantiles
## of the Standard Normal Distribution)
```
Estimate Subgraph around a Response Variable using Preselection

Description
This function uses \texttt{pcSelect} to preselect some covariates and then runs \texttt{pcSelect} again on the reduced data set.

Usage

\texttt{pcSelect.presel(y, dm, alpha, alphapre, corMethod = "standard",
verbosе = 0, directed=FALSE)}

Arguments

\begin{itemize}
  \item \texttt{y} Response vector.
  \item \texttt{dm} Data matrix (rows: samples, cols: nodes; i.e., length(y) == nrow(dm)).
  \item \texttt{alpha} Significance level of individual partial correlation tests.
  \item \texttt{alphapre} Significance level for \texttt{pcSelect} in preselection
  \item \texttt{corMethod} "standard" or "Qn" for standard or robust correlation estimation
  \item \texttt{verbosе} 0-no output, 1-small output, 2-details (using 1 and 2 makes the function very much slower)
  \item \texttt{directed} Logical; should the output graph be directed?
\end{itemize}

Details
First, \texttt{pcSelect} is run using \texttt{alphapre}. Then, only the important variables are kept and \texttt{pcSelect} is run on them again.

Value

\begin{itemize}
  \item \texttt{pcs} Logical vector indicating which column of \texttt{dm} is associated with \texttt{y}
  \item \texttt{zMin} The minimal z-values when testing partial correlations between \texttt{y} and each column of \texttt{dm}. The larger the number, the more consistent is the edge with the data.
  \item \texttt{Xnew} Preselected Variables.
\end{itemize}

dm <- d.mat[,1:9]
res <- pcSelect.psel(d.mat[,10], d.mat[,1:9], alpha=0.05, alphapre=0.6)
```

Description

`pdag2allDags` computes all DAGs in the Markov Equivalence Class Represented by a Given Partially Directed Acyclic Graph (PDAG).

Usage

```r
pdag2allDags(gm, verbose = FALSE)
```

Arguments

- `gm` : adjacency matrix of type `amat.cpdag`
- `verbose` : logical; if true, some output is produced during computation

Details

All DAGs extending the given PDAG are computing while avoiding new v-structures and cycles. If no DAG is found, the function returns `NULL`.

Value

List with two elements:

- `dags` : Matrix; every row corresponds to a DAG; every column corresponds to an entry in the adjacency matrix of this DAG. Thus, the adjacency matrix (of type `amat.cpdag`) contained in the i-th row of matrix `dags` can be obtained by calling `matrix(dags[i,], p, p, byrow = TRUE)` (assuming the input PDAG has `p` nodes).
nodeNms  Node labels of the input PDAG.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

Examples

```r
## Example 1
gm <- rbind(c(0,1),
             c(1,0))
colnames(gm) <- rownames(gm) <- LETTERS[1:2]
res1 <- pdag2allDags(gm)
## adjacency matrix of first DAG in output
amat1 <- matrix(res1$dags[1,],2,2, byrow = TRUE)
colnames(amat1) <- rownames(amat1) <- res1$nodeNms
amat1

## Example 2
gm <- rbind(c(0,1,1),
             c(1,0,1),
             c(1,1,0))
colnames(gm) <- rownames(gm) <- LETTERS[1:ncol(gm)]
res2 <- pdag2allDags(gm)
## adjacency matrix of first DAG in output
amat2 <- matrix(res2$dags[1,],3,3, byrow = TRUE)
colnames(amat2) <- rownames(amat2) <- res2$nodeNms
amat2

## Example 3
gm <- rbind(c(0,1,1,0,0),
             c(1,0,0,0,0),
             c(1,0,0,0,0),
             c(0,1,1,0,1),
             c(0,0,0,1,0))
colnames(gm) <- rownames(gm) <- LETTERS[1:ncol(gm)]
res3 <- pdag2allDags(gm)
## adjacency matrix of first DAG in output
amat3 <- matrix(res3$dags[1,],5,5, byrow = TRUE)
colnames(amat3) <- rownames(amat3) <- res3$nodeNms
amat3

## for convenience a simple plotting function
## for the function output
plotAllDags <- function(res) {
  require(graph)
  p <- sqrt(ncol(res$dags))
  nDags <- ceiling(sqrt(nrow(res$dags)))
  par(mfrow = c(nDags, nDags))
  for (i in 1:nrow(res$dags)) {
    tmp <- matrix(res$dags[i,],p,p)
    colnames(tmp) <- rownames(tmp) <- res$nodeNms
    plot(as(tmp, "graphNEL"))
  }
}
pdag2dag

Extend a Partially Directed Acyclic Graph (PDAG) to a DAG

**Description**

This function extends a PDAG (Partially Directed Acyclic Graph) to a DAG, if this is possible.

**Usage**

```r
pdag2dag(g, keepVstruct=TRUE)
```

**Arguments**

- `g` : Input PDAG (graph object)
- `keepVstruct` : Logical indicating if the v-structures in `g` are kept. Otherwise they are ignored and an arbitrary extension is generated.

**Details**

Direct undirected edges without creating directed cycles or additional v-structures. The PDAG is consistently extended to a DAG using the algorithm by Dor and Tarsi (1992). If no extension is possible, a DAG corresponding to the skeleton of the PDAG is generated and a warning message is produced.

**Value**

List with entries

- `graph` : Contains a consistent DAG extension (graph object),
- `success` : Is TRUE iff the extension was possible.

**Author(s)**

Markus Kalisch <kalisch@stat.math.ethz.ch>

**References**

Examples

```r
p <- 10  # number of random variables
n <- 10000  # number of samples
s <- 0.4  # sparseness of the graph

# Generate random data
set.seed(42)
g <- randomDAG(p, prob = s)  # Generate a random DAG
d <- rmvDAG(n, g)  # Generate random samples

gSkel <- pcAlgo(d, alpha=0.05)  # Estimate of the skeleton
(gPDAG <- udag2pdag(gSkel))
(gDAG <- pdag2dag(gPDAG@graph))
```

Description

Estimate the final skeleton in the FCI algorithm (Spirtes et al., 2000), as described in Steps 2 and 3 of Algorithm 3.1 in Colombo et al. (2012). The input of this function consists of an initial skeleton that was estimated by the PC algorithm (Step 1 of Algorithm 3.1 in Colombo et al. (2012)).

Given the initial skeleton, all unshielded triples are considered and oriented as colliders when appropriate. Then, for all nodes x in the resulting partially directed graph G, Possible-D-SEP(x,G) is computed, using the function qreach. Finally, for any edge y-z that is present in G, conditional independence between Y and Z is tested given all subsets of Possible-D-SEP(y,G) and all subsets of Possible-D-SEP(z,G). These tests are done at level alpha, using indepTest. If the pair of nodes is judged to be independent given some set S, then S is recorded in sepset(y,z) and sepset(z,y) and the edge y-z is deleted. Otherwise, the edge remains and there is no change to sepset.

Usage

```r
pdsep(skel, suffStat, indepTest, p, sepset, alpha, pMax, m.max = Inf, pdsep.max = Inf, NAdelete = TRUE, unfVect = NULL, biCC = FALSE, verbose = FALSE)
```

Arguments

- `skel`: Graph object returned by `skeleton`.
- `suffStat`: Sufficient statistic: A list containing all necessary elements for making conditional independence decisions using function `indepTest`.
- `indepTest`: Predefined function for testing conditional independence. The function is internally called as `indepTest(x, y, S, suffStat)` for testing conditional independence of x and y given S. Here, x and y are node numbers of the adjacency matrix, S is a (possibly empty) vector of node numbers of the adjacency matrix.
and `suffStat` is a list containing all relevant elements for making conditional independence decisions. The return value of `indepTest` is the p-value of the test for conditional independence.

- **p**
  Number of variables.

- **sepset**
  List of length `p`; each element of the list contains another list of length `p`. The element `sepset[[x]][[y]]` contains the separation set that made the edge between `x` and `y` drop out. This object is thought to be obtained from a `pcAlgo-object` or `fciAlgo-object`.

- **alpha**
  Significance level for the individual conditional independence tests.

- **pMax**
  Matrix with the maximal p-values of conditional independence tests in a previous call of `skeleton, pc` or `fci` which produced `G`. This object is thought to be obtained from a `pcAlgo-object` or `fciAlgo-object`.

- **m.max**
  Maximum size of the conditioning sets that are considered in the conditional independence tests.

- **pdsep.max**
  Maximum size of Possible-D-SEP for which subsets are considered as conditioning sets in the conditional independence tests. If the nodes `x` and `y` are adjacent in the graph and the size of Possible-D-SEP(`x,G\{x,y}`) is bigger than `pdsep.max`, the edge is simply left in the graph. Note that if `pdsep.max` is less than Inf, the final PAG is typically a supergraph of the one computed with `pdsep.max = Inf`, because fewer tests may have been performed in the former.

- **NAdelete**
  If `indepTest` returns `NA` and this option is `TRUE`, the corresponding edge is deleted. If this option is `FALSE`, the edge is not deleted.

- **unfVector**
  Vector containing numbers that encode the unfaithful triple (as returned by `pc.cons.intern`). This is needed in the conservative FCI.

- **biCC**
  Logical; if `TRUE`, only nodes on paths between nodes `a` and `c` are considered to be in `sepset(a,c)`. This uses biconnected components, see `biConnComp` from `RBGL`.

- **verbose**
  Logical indicating that detailed output is to be provided.

**Details**

To make the code more efficient, we only perform tests that were not performed in the estimation of the initial skeleton.

Note that the Possible-D-SEP sets are computed once in the beginning. They are not updated after edge deletions, in order to make sure that the output of the algorithm does not depend on the ordering of the variables (see also Colombo and Maathuis (2014)).

**Value**

A list with the following elements:

- **G**
  Updated adjacency matrix representing the final skeleton

- **sepset**
  Updated sepsets

- **pMax**
  Updated matrix containing maximal p-values

- **allPdsep**
  Possible-D-Sep for each node
max.ord  Maximal order of conditioning sets during independence tests
n.edgetests  Number of conditional edgetests performed, grouped by the size of the conditioning set.

Author(s)
Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Diego Colombo.

pMax, biCC= TRUE, verbose = TRUE)
```
plotAG

Plot partial ancestral graphs (PAG)

Description

This function is DEPRECATED! Use the plot method of the fciAlgo class instead.

Usage

plotAG(amat)

Arguments

amat Adjacency matrix (coding 0,1,2,3 for no edge, circle, arrowhead, tail; e.g., amat[a,b] = 2 and amat[b,a] = 3 implies a -> b)

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

See Also

fci

plotSG

Plot the subgraph around a Specific Node in a Graph Object

Description

Plots a subgraph for a specified starting node and a given graph. The subgraph consists of those nodes that can be reached from the starting node by passing no more than a specified number of edges.

Usage

plotSG(graphObj, y, dist, amat = NA, directed = TRUE, plot = requireNamespace("Rgraphviz"), main = , cex.main = 1.25, font.main = par("font.main"), col.main=par("col.main"), ...)

...
Arguments

graphObj  An R object of class graph.
y     (integer) position of the starting node in the adjacency matrix.
dist  Distance of nodes included in subgraph from starting node y.
amat  Precomputed adjacency matrix of type amat.cpdag (optional)
directed  logical indicating if the subgraph should be directed.
plot  logical indicating if the subgraph should be plotted (or just returned). Defaults to true when Rgraphviz is installed.
main  title to be used, with a sensible default; see title.
cex.main, font.main, col.main  optional settings for the main title; see title.
...  optional arguments passed to the plot() from package Rgraphviz.

Details

Commencing at the starting point y the function looks for the neighbouring nodes. Beginning with direct parents and children it will continue hierarchically through the distances to y. Note that the neighbourhood does not depend on edge directions. If directed is true (as per default), the orientation of the edges is taken from the initial graph.

For the plotting, the package Rgraphviz must be installed.

Value

the desired subgraph is returned; invisibly, i.e., via invisible, if plot is true.

Author(s)

Daniel Stekhoven, then Martin Maechler.

Examples

## generate a random DAG:
p <- 10
set.seed(45)
myDAG <- randomDAG(p, prob = 0.3)

if(requireNamespace("Rgraphviz")) {
  ## plot whole the DAG
  plot(myDAG, main = "randomDAG(10, prob = 0.3")

  op <- par(mfrow = c(3,2))
  ## plot the neighbours of node number 8 up to distance 1
  plotSG(myDAG, 8, 1, directed = TRUE)
  plotSG(myDAG, 8, 1, directed = FALSE)

  ## plot the neighbours of node number 8 up to distance 2
  plotSG(myDAG, 8, 2, directed = TRUE)
  plotSG(myDAG, 8, 2, directed = FALSE)
## Description

In a DAG, CPDAG, MAG or PAG determine which nodes are (possible) ancestors of x on definite status or just any paths potentially avoiding given nodes on the paths.

### Usage

```r
possAn(m, x, y = NULL, possible = TRUE, ds = TRUE, type = c("cpdag", "pdag", "dag", "mag", "pag"))
```

### Arguments

- **m**: Adjacency matrix in coding according to type.
- **x**: Node positions of starting nodes.
- **y**: Node positions of nodes through which a path must not go.
- **possible**: If TRUE, possible ancestors are returned.
- **ds**: If TRUE, only paths of definite status are considered.
- **type**: Type of adjacency matrix in `m`. The coding is according to `amatType`.

### Details

Not all possible combinations of the arguments are currently implemented and will issue an error if called.

### Value

Vector of all node positions found as (possible) ancestors of the nodes in `x`.

### Author(s)

Markus Kalisch
See Also
amatType

Examples

```r
## a -- b --> c
amat <- matrix(c(0,1,0, 1,0,1, 0,0,0), 3,3)
colnames amat <- rownames amat <- letters[1:3]
plot(as(t amat), "graphNEL")

possAn(m = amat, x = 3, possible = TRUE, ds = FALSE, type = "pdag") ## all nodes
possAn(m = amat, x = 3, y = 2, possible = TRUE, ds = FALSE, type = "pdag") ## only node 1
```

posDe

Find possible descendants of given node(s).

Description

In a DAG, CPDAG, MAG or PAG determine which nodes are (possible) descendants of x on definite status or just any paths potentially avoiding given nodes on the paths.

Usage

```r
posDe(m, x, y = NULL, possible = TRUE, ds = TRUE,
type = c("cpdag", "pdag", "dag", "mag", "pag"))
```

Arguments

- `m` Adjacency matrix in coding according to type.
- `x` Node positions of starting nodes.
- `y` Node positions of nodes through which a path must not go.
- `possible` If TRUE, possible descendents are returned.
- `ds` If TRUE, only paths of definite status are considered.
- `type` Type of adjacency matrix in `m`. The coding is according to amatType.

Details

Not all possible combinations of the arguments are currently implemented and will issue an error if called.

Value

Vector of all node positions found as (possible) descendents of the nodes in `x`.

Examples
## a -> b -- c
amat <- matrix(c(0,1,0, 0,0,1, 0,0,0), 3,3)
colnames(amat) <- rownames(amat) <- letters[1:3]
plot(as(t(amat), "graphNEL"))

possDe amat x possible = TRUE, ds = FALSE, type = "pdag") ## all nodes
possDe amat x = 1, possible = FALSE, ds = FALSE, type = "pdag") ## only nodes 1 and 2
possDe amat x = 1, y = 2, possible = TRUE, ds = FALSE, type = "pdag") ## only node 1

possibleDe [DEPRECATED] Find possible descendants on definite status paths.

Description
This function is DEPRECATED! Use possDe instead.
In a DAG, CPDAG, MAG or PAG determine which nodes are possible descendants of x on definite status paths.

Usage
possibleDe(amat, x)

Arguments
amat adjacency matrix of type amat.pag
x (integer) position of node x (node of interest) in the adjacency matrix.

Details
A non-endpoint vertex X on a path p in a partial mixed graph is said to be of a definite status if it is either a collider or a definite non-collider on p. The path p is said to be of a definite status if all non-endpoint vertices on the path are of a definite status (see e.g. Maathuis and Colombo (2015), Def. 3.4).
A possible descendant of x can be reached moving to adjacent nodes of x but never going against an arrowhead.

Value
Vector with possible descendents.

qreach

Compute Possible-D-SEP(x,G) of a node x in a PDAG G

Description

Let G be a graph with the following edge types: o-o, o-> or <->, and let x be a vertex in the graph. Then this function computes Possible-D-SEP(x,G), which is defined as follows:

v is in Possible-D-SEP(x,G) iff there is a path p between x and v in G such that for every subpath <s,t,u> of p, t is a collider on this subpath or <s,t,u> is a triangle in G.

Usage

qreach(x, amat, verbose = FALSE)

Arguments

x (integer) position of vertex x in the adjacency matrix of which Possible-D-SEP set is to be computed.
amat Adjacency matrix of type amat.pag.
verbose Logical, asking for details on output

Value

Vector of column positions indicating the nodes in Possible-D-SEP of x.

r.gauss.pardag Generate a Gaussian Causal Model Randomly

Description
Generate a random Gaussian causal model. Parameters specifying the connectivity as well as coefficients and error terms of the corresponding linear structural equation model can be specified. The observational expectation value of the generated model is always 0, meaning that no interception terms are drawn.

Usage
r.gauss.pardag(p, prob, top.sort = FALSE, normalize = FALSE, lbe = 0.1, ube = 1, neg.coef = TRUE, labels = as.character(1:p), lbv = 0.5, ubv = 1)

Arguments
p the number of nodes.
prob probability of connecting a node to another node.
top.sort logical indicating whether the output graph should be topologically sorted, meaning that arrows always point from lower to higher node indices.
normalize logical indicating whether weights and error variances should be normalized such that the diagonal of the corresponding observational covariance matrix is 1.
lbe, ube lower and upper bounds of the absolute values of edge weights.
neg.coef logical indicating whether negative edge weights are also admissible.
labels (optional) character vector of variable (or “node”) names.
lbv, ubv lower and upper bound on error variances of the noise terms in the structural equations.
Details

The underlying directed acyclic graph (DAG) is generated by drawing an undirected graph from an Erdős-Rényi model orienting the edges according to a random topological ordering drawn uniformly from the set of permutations of $p$ variables. This means that any two nodes are connected with (the same) probability $\text{prob}$, and that the connectivity of different pairs of nodes is independent.

A Gaussian causal model can be represented as a set of linear structural equations. The regression coefficients of the model can be represented as "edge weights" of the DAG. Edge weights are drawn uniformly and independently from the interval between $\text{lbw}$ and $\text{ubw}$; if $\text{negNcoef} = \text{TRUE}$, their sign is flipped with probability 0.5. Error variances are drawn uniformly and independently from the interval between $\text{lbv}$ and $\text{ubv}$.

If $\text{normalize} = \text{TRUE}$, the edge weights and error variances are normalized in the end to ensure that the diagonal elements of the observational covariance matrix are all 1; the procedure used is described in Hauser and Bühlmann (2012). Note that in this case the error variances and edge weights are no longer guaranteed to lie in the specified intervals after normalization.

Value

An object of class "GaussParDAG".

Author(s)

Alain Hauser (<alain.hauser@bfh.ch>)

  myDAG <- r.gauss.pardag(p = 10, prob = 0.2, top.sort = FALSE)
  plot(myDAG)
}
```
## randDAG

Random DAG Generation

### Description

Generating random directed acyclic graphs (DAGs) with fixed expected number of neighbours. Several different methods are provided, each intentionally biased towards certain properties. The methods are based on the analogue *.game functions in the igraph package.

### Usage

```r
randDAG(n, d, method = "er", par1=NULL, par2=NULL,
        DAG = TRUE, weighted = TRUE, wFUN = list(runif, min=0.1, max=1))
```

### Arguments

- **n** integer, at least 2, indicating the number of nodes in the DAG.
- **d** a positive number, corresponding to the expected number of neighbours per node, more precisely the expected sum of the in- and out-degree.
- **method** a string, specifying the method used for generating the random graph. See details below.
- **par1, par2** optional additional arguments, dependent on the method. See details.
- **DAG** logical, if TRUE, labelled graph is directed to a labelled acyclic graph.
- **weighted** logical indicating if edge weights are computed according to \( wFUN \).
wFUN a function for computing the edge weights in the DAG. It takes as first argument a number of edges \( m \) for which it returns a vector of length \( m \) containing the weights. Alternatively, \texttt{wFUN} can be a list consisting of the function in the first entry and of further arguments of the function in the additional entries. The default (only if \texttt{weighted} is true) is a uniform weight in \([0, 1]\). See the examples for more.

Details

A (weighted) random graph with \( n \) nodes and expected number of neighbours \( d \) is constructed. For \texttt{DAG=TRUE}, the graph is oriented to a DAG. There are eight different random graph models provided, each selectable by the parameters \texttt{method}, \texttt{parQ}, and \texttt{parR}, with \texttt{method}, a string, taking one of the following values:

- \texttt{regular}: Graph where every node has exactly \( d \) incident edges. \texttt{par1} and \texttt{par2} are not used.
- \texttt{watts}: Watts-Strogatz graph that interpolates between the regular (\texttt{par1=0}) and Erdos-Renyi graph (\texttt{par1=1}). The parameter \texttt{par1} is per default 0.5 and has to be in \((0, 1)\). \texttt{par2} is not used.
- \texttt{er}: Erdos-Renyi graph where every edge is present independently. \texttt{par1} and \texttt{par2} are not used.
- \texttt{power}: A graph with power-law degree distribution with expectation \( d \). \texttt{par1} and \texttt{par2} are not used.
- \texttt{bipartite}: Bipartite graph with at least \( \texttt{par1}\times n \) nodes in group 1 and at most \((1-\texttt{par1})\times n \) nodes in group 2. The argument \texttt{par1} has to be in \([0, 1]\) and is per default 0.5. \texttt{par2} is not used.
- \texttt{barabasi}: A graph with power-law degree distribution and preferential attachment according to parameter \texttt{par1}. It must hold that \texttt{par1} \(\geq 1\) and the default is \texttt{par1=1}. \texttt{par2} is not used.
- \texttt{geometric}: A geometric random graph in dimension \texttt{par1}, where \texttt{par1} can take values from \(\{2, 3, 4, 5\}\) and is per default 2. If \texttt{par2=\texttt{"geo\"}} and \texttt{weighted=TRUE}, then the weights are computed according to the Euclidean distance. There are currently no other option for \texttt{par2} implemented.
- \texttt{interEr}: A graph with \texttt{par1} islands of Erdos-Renyi graphs, every pair of those connected by a certain number of edges proportional to \texttt{par2} (fraction of inter-connectivity). It is required that \( n/s \) be integer and \texttt{par2} in \((0, 1)\). Defaults are \texttt{par1=2} and \texttt{par2=0.25}, respectively.

Value

A graph object of class \texttt{graphNEL}.

Note

The output is not topologically sorted (as opposed to the output of \texttt{randomDAG}).

```

randomDAG

Generate a Directed Acyclic Graph (DAG) randomly

Description

Generate a random Directed Acyclic Graph (DAG). The resulting graph is topologically ordered from low to high node numbers.
randomDAG

Usage

randomDAG(n, prob, lb = 0.1, ub = 1, V = as.character(1:n))

Arguments

n            Number of nodes, \( n \geq 2 \).
prob         Probability of connecting a node to another node with higher topological ordering.
lb, ub       Lower and upper limit of edge weights, chosen uniformly at random, i.e., by runif(.min=lb, max=ub).
V            character vector length \( n \) of node names.

Details

The \( n \) nodes are ordered. Start with first node. Let the number of nodes with higher order be \( k \). Then, the number of neighbouring nodes is drawn as Bin\( (k, \text{prob}) \). The neighbours are then drawn without replacement from the nodes with higher order. For each node, a weight is uniformly sampled from \( \text{lb} \) to \( \text{ub} \). This procedure is repeated for the next node in the original ordering and so on.

Value

An object of class "graphNEL", see graph-class from package graph, with \( n \) named ("1" to "\( n \)") nodes and directed edges. The graph is topologically ordered. Each edge has a weight between \( \text{lb} \) and \( \text{ub} \).

myDAG <- randomDAG(n = 20, prob = 0.2, lb = 0.1, uB = 1)
## require(Rgraphviz)
plot(myDAG)
Estimate an RFCI-PAG using the RFCI Algorithm

Description

Estimate an RFCI-PAG from observational data, using the RFCI-algorithm.

Usage

```r
rfci(suffStat, indepTest, alpha, labels, p,
     skel.method = c("stable", "original", "stable.fast"),
     fixedGaps = NULL, fixedEdges = NULL, NAdelete = TRUE,
     m.max = Inf, rules = rep(TRUE, 10),
     conservative = FALSE, maj.rule = FALSE,
     numCores = 1, verbose = FALSE)
```

Arguments

- `suffStat`: Sufficient statistics: List containing all necessary elements for the conditional independence decisions in the function `indepTest`.
- `indepTest`: Predefined function for testing conditional independence. The function is internally called as `indepTest(x, y, S, suffStat)`, and tests conditional independence of `x` and `y` given `S`. Here, `x` and `y` are variables, and `S` is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). `suffStat` is a list containing all relevant elements for the conditional independence decisions. The return value of `indepTest` is the p-value of the test for conditional independence.
- `alpha`: significance level (number in (0, 1) for the individual conditional independence tests.
- `labels`: (optional) character vector of variable (or “node”) names. Typically preferred to specifying `p`.
- `p`: (optional) number of variables (or nodes). May be specified if `labels` are not, in which case `labels` is set to 1:p.
- `skel.method`: Character string specifying method; the default, "stable" provides an order-independent skeleton, see `skeleton`.
- `fixedGaps`: A logical matrix of dimension p*p. If entry [i, j] or [j, i] (or both) are TRUE, the edge i-j is removed before starting the algorithm. Therefore, this edge is guaranteed to be absent in the resulting graph.
- `fixedEdges`: A logical matrix of dimension p*p. If entry [i, j] or [j, i] (or both) are TRUE, the edge i-j is never considered for removal. Therefore, this edge is guaranteed to be present in the resulting graph.
- `NAdelete`: If `indepTest` returns NA and this option is TRUE, the corresponding edge is deleted. If this option is FALSE, the edge is not deleted.
- `m.max`: Maximum size of the conditioning sets that are considered in the conditional independence tests.
rules Logical vector of length 10 indicating which rules should be used when directing edges. The order of the rules is taken from Zhang (2009).

conservative Logical indicating if the unshielded triples should be checked for ambiguity after the skeleton has been found, similar to the conservative PC algorithm.

maj.rule Logical indicating if the unshielded triples should be checked for ambiguity after the skeleton has been found using a majority rule idea, which is less strict than the conservative.

numCores Specifies the number of cores to be used for parallel estimation of skeleton.

verbose If true, more detailed output is provided.

Details

This function is rather similar to fci. However, it does not compute any Possible-D-SEP sets and thus does not make tests conditioning on subsets of Possible-D-SEP. This makes RFCI much faster than FCI. The orientation rules for v-structures and rule 4 were modified in order to produce an RFCI-PAG which, in the oracle version, is guaranteed to have the correct ancestral relationships.

The first part of the RFCI algorithm is analogous to the PC and FCI algorithm. It starts with a complete undirected graph and estimates an initial skeleton using the function skeleton, which produces an initial order-independent skeleton, see skeleton for more details. All edges of this skeleton are of the form o-o. Due to the presence of hidden variables, it is no longer sufficient to consider only subsets of the neighborhoods of nodes $x$ and $y$ to decide whether the edge $x \circ o \circ y$ should be removed. The FCI algorithm performs independence tests conditioning on subsets of Possible-D-SEP to remove those edges. Since this procedure is computationally infeasible, the RFCI algorithm uses a different approach to remove some of those superfluous edges before orienting the v-structures and the discriminating paths in orientation rule 4.

Before orienting the v-structures, we perform the following additional conditional independence tests. For each unshielded triple $a-b-c$ in the initial skeleton, we check if both $a$ and $b$ and $b$ and $c$ are conditionally dependent given the separating of $a$ and $c$ (sepset$(a,c)$). These conditional dependencies may not have been checked while estimating the initial skeleton, since sepset$(a,c)$ does not need to be a subset of the neighbors of a or of the neighbors of c. If both conditional dependencies hold and $b$ is not in the sepset$(a,c)$, the triple is oriented as a v-structure $a \rightarrow b \leftarrow c$. On the other hand, if an additional conditional independence relationship may be detected, say $a$ is independent from $b$ given the sepset$(a,c)$, the edge between $a$ and $c$ is removed from the graph and the set responsible for that is saved in sepset$(a,b)$. The removal of an edge can destroy or create new unshielded triples in the graph. To solve this problem we work with lists (for details see Colombo et al., 2012).

Before orienting discriminating paths, we perform the following additional conditional independence tests. For each triple $a \leftarrow * b \circ * c$ with $a \rightarrow c$, the algorithm searches for a discriminating path $p = <d, \ldots, a, b, c>$ for $b$ of minimal length, and checks that the vertices in every consecutive pair $(f1,f2)$ on $p$ are conditionally dependent given all subsets of sepset$(d,c) \setminus f1,f2$. If we do not find any conditional independence relationship, the path is oriented as in rule (R4). If one or more conditional independence relationships are found, the corresponding edges are removed, their minimal separating sets are stored.

Conservative RFCI can be computed if the argument of conservative is TRUE. After the final skeleton is computed and the additional local tests on all unshielded triples, as described above, have been done, all potential v-structures $a-b-c$ are checked in the following way. We test whether $a$ and $c$ are independent conditioning on any subset of the neighbors of $a$ or any subset of the
neighbors of c. When a subset makes a and c conditionally independent, we call it a separating set. If b is in no such separating set or in all such separating sets, no further action is taken and the normal version of the RFCI algorithm is continued. If, however, b is in only some separating sets, the triple a-b-c is marked 'ambiguous'. If a is independent of c given some S in the skeleton (i.e., the edge a-c dropped out), but a and c remain dependent given all subsets of neighbors of either a or c, we will call all triples a-b-c 'unambiguous'. This is because in the RFCI algorithm, the true separating set might be outside the neighborhood of either a or c. An ambiguous triple is not oriented as a v-structure. Furthermore, no further orientation rule that needs to know whether a-b-c is a v-structure or not is applied. Instead of using the conservative version, which is quite strict towards the v-structures, Colombo and Maathuis (2014) introduced a less strict version for the v-structures called majority rule. This adaptation can be called using maj.rule = TRUE. In this case, the triple a-b-c is marked as 'ambiguous' if and only if b is in exactly 50 percent of such separating sets or no separating set was found. If b is in less than 50 percent of the separating sets it is set as a v-structure, and if in more than 50 percent it is set as a non v-structure (for more details see Colombo and Maathuis, 2014).

The implementation uses the stabilized skeleton skeleton, which produces an initial order-independent skeleton. The final skeleton and edge orientations can still be order-dependent, see Colombo and Maathuis (2014).

Value

An object of class fciAlgo (see fciAlgo) containing the estimated graph (in the form of an adjacency matrix with various possible edge marks), the conditioning sets that lead to edge removals (sepset) and several other parameters.

```
**Description**

Generate multivariate data with dependency structure specified by a (given) DAG (Directed Acyclic Graph) with nodes corresponding to random variables. The DAG has to be **topologically ordered**.

**Usage**

```r
rmvDAG(n, dag,
  errDist = c("normal", "cauchy", "t4", "mix", "mixt3", "mixN100"),
  mix = 0.1, errMat = NULL, back.compatible = FALSE,
  use.node.names = !back.compatible)
```

**Arguments**

- `n` number of samples that should be drawn. (integer)
- `dag` a graph object describing the DAG; must contain weights for all the edges. The nodes must be topologically sorted. (For topological sorting use `tsort` from the `RBGL` package.)
- `errDist` string specifying the distribution of each node. Currently, the options "normal", "t4", "cauchy", "mix", "mixt3" and "mixN100" are supported. The first three generate standard normal-, t(df=4)- and cauchy-random numbers. The options containing the word "mix" create standard normal random variables with a mix of outliers. The outliers for the options "mix", "mixt3", "mixN100" are drawn from a standard cauchy, t(df=3) and N(0,100) distribution, respectively. The fraction of outliers is determined by the `mix` argument.
- `mix` for the "mix*" error distribution, `mix` specifies the fraction of "outlier" samples (i.e., Cauchy, t3 or N(0,100)).
- `errMat` numeric n*p matrix specifying the error vectors $e_i$ (see Details), instead of specifying `errDist` (and maybe `mix`).
- `back.compatible` logical indicating if the data generated should be the same as with `pcalg` version 1.0-6 and earlier (where `wgtMatrix()` differed).
- `use.node.names` logical indicating if the column names of the result matrix should equal `nodes(dag)`, very sensibly, but new, hence the default.

**Details**

Each node is visited in the topological order. For each node $i$ we generate a $p$-dimensional value $X_i$ in the following way: Let $X_1, \ldots, X_k$ denote the values of all neighbours of $i$ with lower order. Let $w_1, \ldots, w_k$ be the weights of the corresponding edges. Furthermore, generate a random vector $E_i$ according to the specified error distribution. Then, the value of $X_i$ is computed as

$$X_i = w_1 * X_1 + \ldots + w_k * X_k + E_i.$$

If node $i$ has no neighbors with lower order, $X_i = E_i$ is set.
Value

A $n \times p$ matrix with the generated data. The $p$ columns correspond to the nodes (i.e., random variables) and each of the $n$ rows correspond to a sample.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>) and Martin Maechler.

See Also

`randomDAG` for generating a random DAG; `skeleton` and `pc` for estimating the skeleton and the CPDAG of a DAG that corresponds to the data.

Examples

```r
## generate random DAG
p <- 20
rDAG <- randomDAG(p, prob = 0.2, lB=0.1, uB=1)

if (require(Rgraphviz)) {
  ## plot the DAG
  plot(rDAG, main = "randomDAG(20, prob = 0.2, ..")
}

## generate 1000 samples of DAG using standard normal error distribution
n <- 1000
d.normMat <- rmvDAG(n, rDAG, errDist="normal")

## generate 1000 samples of DAG using standard t(df=4) error distribution
d.t4Mat <- rmvDAG(n, rDAG, errDist="t4")

## generate 1000 samples of DAG using standard normal with a cauchy mixture of 30 percent
## mixture of 30 percent

d.mixMat <- rmvDAG(n, rDAG, errDist="mix",mix=0.3)

require(MASS) ## for mvrnorm()
Sigma <- toeplitz(ARMAacf(0.2, lag.max = p - 1))
dim(Sigma)# p x p
## *Correlated* normal error matrix "e_i" (against model assumption)
eMat <- mvrnorm(n, mu = rep(0, p), Sigma = Sigma)
d.CnormMat <- rmvDAG(n, rDAG, errMat = eMat)
```

---

**rmvnorm.ivent**

Simulate from a Gaussian Causal Model

**Description**

Produces one or more samples from the observational or an interventional distribution associated to a Gaussian causal model.
Score-class

Usage

```
rmvnorm.ient(n, object, target = integer(0), target.value = numeric(0))
```

Arguments

- `n`: Number of samples required.
- `object`: An instance of `GaussParDAG`.
- `target`: Intervention target: vector of intervened nodes. If the vector is empty, samples from the observational distribution are generated. Otherwise, samples from an interventional distribution are simulated.
- `target.value`: Values of the intervened variables. If `target.value` is a vector of the same length as `target`, the indicated intervention levels are used for all `n` samples. If `target.value` is a matrix of dimension `n` by `length(target)`, the `i`-th sample is simulated using the `i`-th row of the matrix as intervention levels.

Value

If `n == 1` a vector of length `p` is returned, where `p` denotes the number of nodes of `object`. Otherwise an `n` by `p` matrix is returned with one sample per row.

Author(s)

Alain Hauser (<alain.hauser@bfh.ch>)

Examples

```
set.seed(307)
myDAG <- r.gauss.pardag(5, 0.5)
var(rmvnorm.ient(n = 1000, myDAG))
myDAG$cov.mat()
var(rmvnorm.ient(n = 1000, myDAG, target = 1, target.value = 1))
myDAG$cov.mat(target = 1, ient.var = 0)
```

Score-class

Virtual Class "Score"

Description

This virtual base class represents a score for causal inference; it is used in the causal inference functions `ges`, `gies` and `simy`. 
Details

Score-based structure learning algorithms for causal inference such as Greedy Equivalence Search (GES, implemented in the function `ges`), Greedy Interventional Equivalence Search (GIES, implemented in the function `gies`) and the dynamic programming approach of Silander and Myllymäki (2006) (implemented in the function `simy`) try to find the DAG model which maximizes a scoring criterion for a given data set. A widely-used scoring criterion is the Bayesian Information Criterion (BIC).

The virtual class `Score` is the base class for providing a scoring criterion to the mentioned causal inference algorithms. It does not implement a concrete scoring criterion, but it defines the functions that must be provided by its descendants (cf. methods).

Knowledge of this class is only required if you aim to implement an own scoring criterion. At the moment, it is recommended to use the predefined scoring criteria for multivariate Gaussian data derived from `Score`, `GaussL0penIntScore` and `GaussL0penObsScore`.

Fields

The fields of `Score` are mainly of interest for users who aim at deriving an own class from this virtual base class, i.e., implementing an own score function.

- `.nodes`: Node labels. They are passed to causal inference methods by default to label the nodes of the resulting graph.
- `.decomp`: Indicates whether the represented score is decomposable (cf. details). At the moment, only decomposable scores are supported by the implementation of the causal inference algorithms; support for non-decomposable scores is planned.
- `.pp.dat`: List representing the preprocessed input data; this is typically a statistic which is sufficient for the calculation of the score.
- `p dag.class`: Name of the class of the parametric DAG model corresponding to the score. This must name a class derived from `ParDAG`.
- `.fcn`: Only used internally; must remain empty for (user specified) classes derived from `Score`.

Constructor

```r
new("Score",
  data = matrix(1, 1, 1),
  targets = list(integer(0)),
  target.index = rep(as.integer(1), nrow(data)),
  nodes = colnames(data),
  ...
)
```

data Data matrix with \( n \) rows and \( p \) columns. Each row corresponds to one realization, either interventional or observational.

targets List of mutually exclusive intervention targets that have been used for data generation.
target.index Vector of length \( n \); the \( i \)-th entry specifies the index of the intervention target in targets under which the \( i \)-th row of data was measured.
nodes Node labels

... Additional parameters used by derived (and non-virtual) classes.
Methods

Note that since Score is a virtual class, its methods cannot be called directly, but only on derived classes.

local.score(vertex, parents, ...) For decomposable scores, this function calculates the local score of a vertex and its parents. Must throw an error in derived classes that do not represent a decomposable score.

global.score.int(edges, ...) Calculates the global score of a DAG, represented as a list of in-edges: for each vertex in the DAG, this list contains a vector of parents.

global.score(dag, ...) Calculates the global score of a DAG, represented as object of a class derived from ParDAG.

local.fit(vertex, parents, ...) Calculates a local model fit of a vertex and its parents, e.g. by MLE. The result is a vector of parameters whose meaning depends on the model class; it matches the convention used in the corresponding causal model (cf. .pardag.class).

global.fit(dag, ...) Calculates the global MLE of a DAG, represented by an object of the class specified by .pardag.class. The result is a list of vectors, one per vertex, each in the same format as the result vector of local.mle.

shd

Compute Structural Hamming Distance (SHD)

Description

Compute the Structural Hamming Distance (SHD) between two graphs. In simple terms, this is the number of edge insertions, deletions or flips in order to transform one graph to another graph.

Usage

shd(g1,g2)
showAmat

Arguments

- \( g1 \) : Graph object
- \( g2 \) : Graph object

Value

The value of the SHD (numeric).

Author(s)

Markus Kalisch <kalisch@stat.math.ethz.ch> and Martin Maechler

References

Examples

```r
## generate two graphs
g1 <- randomDAG(10, prob = 0.2)
g2 <- randomDAG(10, prob = 0.2)
## compute SHD
(shd.val <- shd(g1, g2))
```

Description

This function is deprecated - Use `as(*, "amat")` instead!

Show the adjacency matrix of a "pcAlgo" object; this is intended to be an alternative if the `Rgraphviz` package does not work.

Usage

`showAmat(object)`

Arguments

- `object` : an \( \mathcal{R} \) object of class `pcAlgo`, as returned from `skeleton()` or `pc()`.

Value

The adjacency matrix.
Note

For "fciAlgo" objects, the show method produces a similar result.

Author(s)

Markus Kalisch (<kalisch@stat.math.ethz.ch>)

See Also

showEdgeList for showing the edge list of a pcAlgo object. iplotPC for plotting a "pcAlgo" object using the package igraph also for an example of showamat().

Description

Show the list of edges (of the graph) of a pcAlgo object; this is intended to be an alternative if Rgraphviz does not work.

Usage

showEdgeList(object, labels = NULL)

Arguments

object an R object of class pcAlgo, as returned from skeleton() or pc().
labels optional labels for nodes; by default, the labels from the object are used.

Value

none; the purpose is in (the side effect of) printing the edge list.

Note

This is not quite ok for "fciAlgo" objects, yet.

**Description**

Estimate the interventional essential graph representing the Markov equivalence class of a DAG using the dynamic programming (DP) approach of Silander and Myllymäki (2006). This algorithm maximizes a decomposable scoring criterion in exponential runtime.

**Usage**

```r
simy(score, labels = score$getNodes(), targets = score$getTargets(),
    verbose = FALSE, ...)
```

**Arguments**

- `score`: An instance of a class derived from `Score`.
- `labels`: Node labels; by default, they are determined from the scoring object.
- `targets`: A list of intervention targets (cf. details). A list of vectors, each vector listing the vertices of one intervention target.
- `verbose`: if `TRUE`, detailed output is provided.
- `...`: Additional arguments for debugging purposes and fine tuning.

**Details**

This function estimates the interventional Markov equivalence class of a DAG based on a data sample with interventional data originating from various interventions and possibly observational data. The intervention targets used for data generation must be specified by the argument `targets` as a list of (integer) vectors listing the intervened vertices; observational data is specified by an empty set, i.e. a vector of the form `integer(0)`. As an example, if data contains observational samples as well as samples originating from an intervention at vertices 1 and 4, the intervention targets must be specified as `list(integer(0), as.integer(1), as.integer(c(1, 4)))`.

An interventional Markov equivalence class of DAGs can be uniquely represented by a partially directed graph called interventional essential graph. Its edges have the following interpretation:

1. a directed edge $a \rightarrow b$ stands for an arrow that has the same orientation in all representatives of the interventional Markov equivalence class;
2. an undirected edge $a - b$ stands for an arrow that is oriented in one way in some representatives of the equivalence class and in the other way in other representatives of the equivalence class.

Note that when plotting the object, undirected and bidirected edges are equivalent.

The DP approach of Silander and Myllymäki (2006) is a score-based algorithm that guarantees to find the optimum of any decomposable scoring criterion. Its CPU and memory consumption grow exponentially with the number of variables in the system, irrespective of the sparseness of the true or estimated DAG. The implementation in the pcalg package is feasible up to approximately 20 variables, depending on the user’s computer.
Value

`simy` returns a list with the following two components:

- `essgraph`: An object of class `EssGraph` containing an estimate of the equivalence class of the underlying DAG.
- `repr`: An object of a class derived from `ParDAG` containing a (random) representative of the estimated equivalence class.

}
```
Estimate (Initial) Skeleton of a DAG using the PC / PC-Stable Algorithm

Description

Estimate the skeleton of a DAG without latent and selection variables using the PC Algorithm or estimate an initial skeleton of a DAG with arbitrarily many latent and selection variables using the FCI and the RFCI algorithms.

If used in the PC algorithm, it estimates the order-independent “PC-stable” ("stable") or original PC ("original") “skeleton” of a directed acyclic graph (DAG) from observational data.

When used in the FCI and RFCI algorithms, this function estimates only an initial order-independent (or PC original) “skeleton”. Because of the presence of latent and selection variables, to find the final skeleton those algorithms need to perform additional tests later on and consequently some edges can be further deleted.

Usage

skeleton(suffStat, indepTest, alpha, labels, p, method = c("stable", "original", "stable.fast"), m.max = Inf, fixedGaps = NULL, fixedEdges = NULL, NAdelete = TRUE, num_cores = 1, verbose = FALSE)

Arguments

suffStat  Sufficient statistics: List containing all necessary elements for the conditional independence decisions in the function indepTest.

indepTest  Predefined function for testing conditional independence. The function is internally called as indepTest(x, y, S, suffStat) and tests conditional independence of x and y given S. Here, x and y are variables, and S is a (possibly empty) vector of variables (all variables are denoted by their column numbers in the adjacency matrix). suffStat is a list containing all relevant elements for the conditional independence decisions. The return value of indepTest is the p-value of the test for conditional independence.

alpha  significance level (number in (0, 1) for the individual conditional independence tests.

labels  (optional) character vector of variable (or “node”) names. Typically preferred to specifying p.

p  (optional) number of variables (or nodes). May be specified if labels are not, in which case labels is set to 1:p.

method  Character string specifying method; the default, "stable" provides an order-independent skeleton, see ‘Details’ below.

m.max  Maximal size of the conditioning sets that are considered in the conditional independence tests.
fixedGaps logical symmetric matrix of dimension p*p. If entry [i, j] is true, the edge i \rightarrow j is removed before starting the algorithm. Therefore, this edge is guaranteed to be absent in the resulting graph.

fixedEdges a logical symmetric matrix of dimension p*p. If entry [i, j] is true, the edge i \rightarrow j is never considered for removal. Therefore, this edge is guaranteed to be present in the resulting graph.

NAdelete logical needed for the case indepTest(*) returns NA. If it is true, the corresponding edge is deleted, otherwise not.

numCores number of processor cores to use for parallel computation. Only available for method = "stable.fast".

verbose if TRUE, detailed output is provided.

Details

Under the assumption that the distribution of the observed variables is faithful to a DAG and that there are no latent and selection variables, this function estimates the skeleton of the DAG. The skeleton of a DAG is the undirected graph resulting from removing all arrowheads from the DAG. Edges in the skeleton of a DAG have the following interpretation:

There is an edge between i and j, i \rightarrow j, if and only if variables i and j are conditionally dependent given S for all possible subsets S of the remaining nodes.

On the other hand, the distribution of the observed variables is faithful to a DAG with arbitrarily many latent and selection variables, skeleton() estimates the initial skeleton of the DAG. Edges in this initial skeleton of a DAG have the following interpretation:

There is an edge i \rightarrow j if and only if variables i and j are conditionally dependent given S for all possible subsets S of the neighbours of i and the neighbours of j.

The data are not required to follow a specific distribution, but one should make sure that the conditional independence test used in indepTest is appropriate for the data. Pre-programmed versions of indepTest are available for Gaussian data (gaussCtTest), discrete data (discCtTest), and binary data (see bincTest). Users may also specify their own indepTest function.

The PC algorithm (Spirtes, Glymour and Scheines, 2000) (method = "original") is known to be order-dependent, in the sense that the output may depend on the order in which the variables are given. Therefore, Colombo and Maathuis (2014) proposed a simple modification, called “PC-stable”, which yields order-independent adjacencies in the skeleton, provided by pc() with the new default method = "stable". This stable variant of the algorithm is also available with the method = "stable.fast": it runs the algorithm of Colombo and Maathuis (2014) faster than method = "stable" in general, but should be regarded as an experimental option at the moment.

The algorithm starts with a complete undirected graph. In each step, it visits all pairs (i, j) of adjacent nodes in the current graph, and determines based on conditional independence tests whether the edge i \rightarrow j should be removed. In particular, for each step m (m = 0, 1, . . .) of the size of the conditioning sets, the algorithm at first determines the neighbours a(i) of each node i in the graph. Then, the algorithm visits all pairs (i, j) of adjacent nodes in the current graph, and the edge i \rightarrow j is kept if and only if the null hypothesis i and j are conditionally independent given S rejected at significance level alpha for all subsets S of size m of a(i) and of a(j) (as judged by the function indepTest). For the "stable" method, the neighborhoods a(i) are kept fixed within each value of m, and this makes the algorithm order-independent. Method "original", the original PC algorithm would update the neighbour list after each edge change.
The algorithm stops when \( m \) is larger than the largest neighbourhood size of all nodes, or when \( m \) has reached the limit \( m_{\text{max}} \) which may be set by the user.

Since the FCI (Spirtes, Glymour and Scheines, 2000) and RFCI (Colombo et al., 2012) algorithms are built up from the PC algorithm, they are also order-dependent in the skeleton. To resolve their order-dependence issues in the skeleton is more involved, see Colombo and Maathuis (2014). However now, with method = "stable", this function estimates an initial order-independent skeleton in these algorithms (for additional details on how to make the final skeleton of FCI fully order-independent see fci and Colombo and Maathuis (2014)).

The information in fixedGaps and fixedEdges is used as follows. The gaps given in fixedGaps are introduced in the very beginning of the algorithm by removing the corresponding edges from the complete undirected graph. Pairs \((i,j)\) in fixedEdges are skipped in all steps of the algorithm, so that these edges remain in the graph.

Note: Throughout, the algorithm works with the column positions of the variables in the adjacency matrix, and not with the names of the variables.

**Value**

An object of class "pcAlgo" (see pcAlgo) containing an estimate of the skeleton of the underlying DAG, the conditioning sets (sepset) that led to edge removals and several other parameters.

trueCov

Covariance matrix of a DAG.

Description

Compute the (true) covariance matrix of a generated DAG.

Usage

trueCov(dag, back.compatible = FALSE)

Arguments

dag

Graph object containing the DAG.

back.compatible

logical indicating if the data generated should be the same as with pcalg version 1.0-6 and earlier (where wgtMatrix() differed).

Value

Covariance matrix.

Note

This function can not be used to estimate the covariance matrix from an estimated DAG or corresponding data.

g <- randomDAG(n = 5, prob = 0.3) ## generate random DAG
if(require(Rgraphviz)) {
  plot(g)
}

## Compute true covariance matrix
trueCov(g)

## For comparison:
## Estimate true covariance matrix after generating data from g
d <- rmvDAG(10000, g)
cov(d)
```

Description

This function performs the last step of the RFCI algorithm: It transforms a partially oriented graph in which the v-structures have been oriented into an RFCI Partial Ancestral Graph (PAG) (see Colombo et al (2012)).

While orienting the edges, this function performs some additional conditional independence tests in orientation rule 4 to ensure correctness of the ancestral relationships. As a result of these additional tests, some additional edges can be deleted. The result is the final adjacency matrix indicating also the edge marks and the updated sepsets.

Usage

```r
udag2apag(apag, suffStat, indepTest, alpha, sepset, rules = rep(TRUE, 10), unfVect = NULL, verbose = FALSE)
```

Arguments

- **apag** Adjacency matrix of type `amat.pag`
- **suffStat** Sufficient statistics: A **list** containing all necessary elements for the conditional independence decisions in the function `indepTest`.
**indeptest**

Pre-defined function for testing conditional independence. The function is internally called as `indeptest(x, y, S, suffStat)`, and tests conditional independence of $x$ and $y$ given $S$. Here, $x$ and $y$ are variables, and $S$ is a (possibly empty) set of variables (all variables are coded by their column numbers in the adjacency matrix). `suffStat` is a list containing all relevant elements for the conditional independence decisions. The return value of `indeptest` is the p-value of the test for conditional independence.

**alpha**

Significance level for the individual conditional independence tests.

**sepset**

List of length $p$; each element of the list contains another list of length $p$. The element `sepset[[x]][[y]]` contains the separation set that made the edge between $x$ and $y$ drop out. Each separation set is a vector with (integer) positions of variables in the adjacency matrix. This object is thought to be obtained from a `pcAlgo-object`.

**rules**

Logical vector of length 10 with `TRUE` or `FALSE` for each rule, where `TRUE` in position $i$ means that rule $i$ (R$i$) will be applied. By default, all rules are active.

**unfVect**

Vector containing numbers that encode the ambiguous triples (as returned by `pc.cons.intern`). This is needed in the conservative and in the majority rule versions of RFCI.

**verbose**

Logical indicating if detailed output is to be given.

**Details**

The partially oriented graph in which the v-structures have been oriented is transformed into an RFCI-PAG using adapted rules of Zhang (2008). This function is similar to `udag2pag` used to orient the skeleton into a PAG in the FCI algorithm. However, it is slightly more complicated because we perform additional conditional independence tests when applying rule 4, to ensure correctness of the ancestral relationships. As a result, some additional edges can be deleted, see Colombo et al. (2012). Because of these additional tests, we need to give `suffStat`, `indeptest`, and `alpha` as inputs. Since edges can be deleted, the input adjacency matrix `apag` and the input separating sets `sepset` can change in this algorithm.

If `unfVect = NULL` (no ambiguous triples), the orientation rules are applied to each eligible structure until no more edges can be oriented. On the other hand, if one uses conservative or majority rule FCI and ambiguous triples have been found in `pc.cons.intern`, `unfVect` contains the numbers of all ambiguous triples in the graph. In this case, the orientation rules take this information into account. For example, if a $* \to b$ o-$*$ c and $<a,b,c>$ is an unambiguous unshielded triple and not a v-structure, then we obtain $b \to c$ (otherwise we would create an additional v-structure). On the other hand, if a $* \to b$ o-$*$ c but $<a,b,c>$ is an ambiguous unshielded triple, then the circle mark at $b$ is not oriented.

Note that the algorithm works with columns’ position of the adjacency matrix and not with the names of the variables.

Note that this function does not resolve possible order-dependence in the application of the orientation rules, see Colombo and Maathuis (2014).

**Value**

| apag | Final adjacency matrix of type `amat.pag` |
| sepset | Updated list of separating sets |

**udag2pag**

*Last steps of FCI algorithm: Transform Final Skeleton into FCI-PAG*

**Description**

This function perform the last steps of the FCI algorithm, as it transforms an un-oriented final skeleton into a Partial Ancestral Graph (PAG). The final skeleton must have been estimated with `pdsep()`. The result is an adjacency matrix indicating also the edge marks.

**Usage**

```
udag2pag(pag, sepset, rules = rep(TRUE, 10), unfVect = NULL,
         verbose = FALSE, orientCollider = TRUE)
```

**Arguments**

- **pag**  Adjacency matrix of type `amat.pag`
sepset List of length p; each element of the list contains another list of length p. The element sepset[[x]][[y]] contains the separation set that made the edge between x and y drop out. Each separation set is a vector with (integer) positions of variables in the adjacency matrix. This object is thought to be obtained from a pcAlgo-object.

rules Array of length 10 containing TRUE or FALSE for each rule. TRUE in position i means that rule i (Ri) will be applied. By default, all rules are used.

unfVect Vector containing numbers that encode ambiguous unshielded triples (as returned by pc.cons.intern). This is needed in the conservative and majority rule versions of FCI.

verbose If TRUE, detailed output is provided.

orientCollider if TRUE, collider are oriented.

Details

The skeleton is transformed into an FCI-PAG using rules by Zhang (2008).

If unfVect = NULL (i.e., one uses standard FCI or one uses conservative/majority rule FCI but there are no ambiguous triples), then the orientation rules are applied to each eligible structure until no more edges can be oriented. On the other hand, if one uses conservative or majority rule FCI and ambiguous triples have been found in pc.cons.intern, unfVect contains the numbers of all ambiguous triples in the graph. In this case, the orientation rules take this information into account. For example, if a *-> b o-* c and <a,b,c> is an unambiguous unshielded triple and not a v-structure, then we obtain b -* c (otherwise we would create an additional v-structure). On the other hand, if a *-> b o-* c but <a,b,c> is an ambiguous unshielded triple, then the circle mark at b is not oriented.

Note that the algorithm works with columns’ position of the adjacency matrix and not with the names of the variables.

Note that this function does not resolve possible order-dependence in the application of the orientation rules, see Colombo and Maathuis (2014).

Value

Adjacency matrix of type amat.pag.

**udag2pdag**

**Last PC Algorithm Step: Extend Object with Skeleton to Completed PDAG**

**Description**

These functions perform the last step in the PC algorithm: Transform an object of the class "pcAlgo" containing a skeleton and corresponding conditional independence information into a completed partially directed acyclic graph (CPDAG). The functions first determine the v-structures, and then apply the three orientation rules as described in Sprirtes et al (2000) and Meek (1995) to orient as many of the remaining edges as possible.

In the oracle version and when all assumptions hold, all three functions yield the same CPDAG. In the sample version, however, the resulting CPDAG may be invalid in the sense that one cannot extend it a DAG without additional unshielded colliders by orienting the undirecting edges. This can for example happen due to errors in the conditional indepedence tests or violations of the faithfulness assumption. The three functions deal with such conflicts in different ways, as described in Details.

**Usage**

```
udag2pdag (gInput, verbose)
udag2pdagRelaxed(gInput, verbose, unfVect=NULL, solve.conf1=FALSE,
               orientCollider = TRUE, rules = rep(TRUE, 3))
udag2pdagSpecial(gInput, verbose, n.max=100)
```

**Arguments**

- **gInput**: "pcAlgo"-object containing skeleton and conditional independence information.
- **verbose**: 0: No output; 1: Details
- **unfVect**: vector containing numbers that encode ambiguous triples (as returned by `pc.cons.intern`). This is needed in the conservative and majority rule PC algorithms.
solve.conf1 if TRUE, the orientation of the v-structures and the orientation rules work with lists for candidate sets and allow bi-directed edges to resolve conflicting edge orientations. Note that therefore the resulting object is order-independent but might not be a PDAG because bi-directed edges can be present.

n.max maximum number of tries for re-orienting doubly visited edges in udag2pdagSpecial.

orientCollider if TRUE, collider are oriented.

rules Array of length 3 containing TRUE or FALSE for each rule. TRUE in position i means that rule i (Ri) will be applied. By default, all rules are used.

Details

for udag2pdag: If there are edges that are part of more than one v-structure (i.e., the edge b - c in the v-structures a -> b <- c and b -> c <- d), earlier edge orientations are simply overwritten by later ones. Thus, if a -> b <- c is considered first, the edge b - c is first oriented as b <- c and later overwritten by b -> c. The v-structures are considered in lexicographical ordering. If the resulting graph is extendable to a DAG without additional v-structures, then the rules of Meek (1995) and Spirtes et al (2000) are applied to obtain the corresponding CPDAG. Otherwise, the edges are oriented randomly to obtain a DAG that fits on the skeleton, discarding all information about the v-structures. The resulting DAG is then transformed into its CPDAG. Note that the output of udag2pdag is random whenever the initial graph was not extendable.

Although the output of udag2pdag is always extendable, it is not necessarily a valid CPDAG in the sense that it describes a Markov equivalence class of DAGs. For example, two v-structures a -> b <- c and b -> c <- d (considered in this order) would yield the output a -> b -> c <- d. This is extendable to a DAG (it already is a DAG), but it does not describe a Markov equivalence class of DAGs, since the DAG a <- b -> c <- d describes the same conditional independencies.

for udag2pdagSpecial: If the graph after orienting the v-structures as in udag2pdag is extendable to a DAG without additional v-structures, then the rules of Meek (1995) and Spirtes et al (2000) are applied to obtain the corresponding CPDAG. Otherwise, the algorithm tries at most n.max different random orderings of the v-structures (hence overwriting orientations in different orders), until it finds one that yields an extendable CPDAG. If this fails, the edges are oriented randomly to obtain a DAG that fits on the skeleton, discarding all information about the v-structures. The resulting DAG is then transformed into its CPDAG. Note that the output of udag2pdagSpecial is random whenever the initial graph was not extendable.

Although the output of udag2pdag is always extendable, it is not necessarily a valid CPDAG in the sense that it describes a Markov equivalence class of DAGs. For example, two v-structures a -> b <- c and b -> c <- d (considered in this order) would yield the output a -> b -> c <- d. This is extendable to a DAG (it already IS a DAG), but it does not describe a Markov equivalence class of DAGs, since the DAG a <- b -> c <- d describes the same conditional independencies.

for udag2pdagRelaxed: This is the default version in the PC/RFCI/FCI algorithm. It does not test whether the output is extendable to a DAG without additional v-structures.

If unfVect = NULL (no ambiguous triples), the three orientation rules are applied to each eligible structure until no more edges can be oriented. Otherwise, unfVect contains the numbers of all ambiguous triples in the graph as determined by pc.cons.intern. Then the orientation rules take this information into account. For example, if a -> b - c and <a,b,c> is an unambiguous triple and a non-v-structure, then rule 1 implies b -> c. On the other hand, if a -> b - c but <a,b,c> is an ambiguous triple, then the edge b - c is not oriented.
If `solveNconfl = FALSE`, earlier edge orientations are overwritten by later ones as in `udag2pdag` and `udag2pdagSpecial`.

If `solveNconfl = TRUE`, both the v-structures and the orientation rules work with lists for the candidate edges and allow bi-directed edges if there are conflicting orientations. For example, two v-structures `a -> b <- c` and `b -> c <- d` then yield `a -> b <-> c <-> d`. This option can be used to get an order-independent version of the PC algorithm (see Colombo and Maathuis (2014)).

We denote bi-directed edges, for example between two variables `i` and `j`, in the adjacency matrix `M` of the graph as `M[i,j]=2` and `M[j,i]=2`. Such edges should be interpreted as indications of conflicts in the algorithm, for example due to errors in the conditional independence tests or violations of the faithfulness assumption.

**Value**

```r
for udag2pdag() and udag2pdagRelaxed(): oriented "pcAlgo"-object.
for udag2pdagSpecial: a list with components
  pcObj An oriented "pcAlgo"-object.
  evisit Matrix counting the number of orientation attempts per edge
  xtbl.orig Logical indicating whether the original graph with v-structures is extendable.
  xtbl Logical indicating whether the final graph with v-structures is extendable
  amat0 Adjacency matrix of original graph with v-structures (type amat.cpdag).
  amat1 Adjacency matrix of final graph with v-structures after changing the ordering in which the v-structures are considered (type amat.cpdag).
  status Integer code with values
    0: Original try is extendable;
    1: Reorienting double edge visits helps;
    2: Original try is not extendable; reorienting double visits does not help; result is acyclic, has original v-structures, but perhaps additional v-structures.
  counter Number of orderings of the v-structures until success or `n.max`.
```

resD3 <- udag2pdag (resU, verbose=0)
```

visibleEdge

Check visible edge.

Description

Check if the directed edge from x to z in a MAG or in a PAG is visible or not.

Usage

`visibleEdge(amat, x, z)`

Arguments

- `amat`  Adjacency matrix of type `amat.pag`
- `x, z`  (integer) position of variable `x` and `z`, respectively, in the adjacency matrix.

Details

All directed edges in DAGs and CPDAGs are said to be visible. Given a MAG M / PAG P, a directed edge A -> B in M / P is visible if there is a vertex C not adjacent to B, such that there is an edge between C and A that is into A, or there is a collider path between C and A that is into A and every non-endpoint vertex on the path is a parent of B. Otherwise A -> B is said to be invisible. (see Maathuis and Colombo (2015), Def. 3.1)

Value

TRUE if edge is visible, otherwise FALSE.
wgtMatrix 163

wgtMatrix

Weight Matrix of a Graph, e.g., a simulated DAG

Description

Given a graph object g, as generated e.g., by randomDAG, return the matrix of its edge weights, the “weight matrix”.

Usage

wgtMatrix(g, transpose = TRUE)

Arguments

g graph object (package graph) of, say, p nodes, e.g. containing a DAG.
transpose logical indicating if the weight matrix should be transposed (t(.), see details).
Details

When generating a DAG (e.g. using `randomDAG`), a graph object is usually generated and edge weights are usually specified. This function extracts the edge weights and arranges them in a matrix $M$.

If `transpose` is `TRUE` (default), $M[i,j]$ is the weight of the edge from $j$ to $i$. If `transpose` is false, $M[i,j]$ is the weight of the edge from $i$ to $j$.

Nowadays, this is a trivial wrapper around `as(g, "matrix")` using the `coerce` method provided by the `graph` package.

Value

The $p \times p$ weight matrix $M$.

Note

This function can not be used to estimate the edge weights in an estimated DAG / CPDAG.
