Package ‘rms’

October 14, 2022

Version 6.3-0
Date 2022-04-12
Title Regression Modeling Strategies
Author Frank E Harrell Jr <fh@fharrell.com>
Maintainer Frank E Harrell Jr <fh@fharrell.com>
Depends R (>= 3.5.0), Hmisc (>= 4.7-0), survival (>= 3.1-12), lattice,
     ggplot2 (>= 2.2), SparseM
Imports methods, quantreg, rpart, nlme (>= 3.1-123), polspline,
     multcomp, htmlTable (>= 1.11.0), htmltools, MASS, cluster,
     digest
Suggests boot, tcltk, plotly (>= 4.5.6), knitr, mice, rmsb, nnet, VGAM
Description Regression modeling, testing, estimation, validation,
     graphics, prediction, and typesetting by storing enhanced model design
     attributes in the fit. ‘rms’ is a collection of functions that
     assist with and streamline modeling. It also contains functions for
     binary and ordinal logistic regression models, ordinal models for
     continuous Y with a variety of distribution families, and the Buckley-James
     multiple regression model for right-censored responses, and implements
     penalized maximum likelihood estimation for logistic and ordinary
     linear models. ‘rms’ works with almost any regression model, but it
     was especially written to work with binary or ordinal regression
     models, Cox regression, accelerated failure time models,
     ordinary linear models, the Buckley-James model, generalized least
     squares for serially or spatially correlated observations, generalized
     linear models, and quantile regression.

Description

The `anova` function automatically tests most meaningful hypotheses in a design. For example, suppose that age and cholesterol are predictors, and that a general interaction is modeled using a restricted spline surface. `anova` prints Wald statistics (F statistics for an ols fit) for testing linearity of age, linearity of cholesterol, age effect (age + age by cholesterol interaction), cholesterol effect (cholesterol + age by cholesterol interaction), linearity of the age by cholesterol interaction (i.e., adequacy of the simple age * cholesterol 1 d.f. product), linearity of the interaction in age alone, and linearity of the interaction in cholesterol alone. Joint tests of all interaction terms in the model and all nonlinear terms in the model are also performed. For any multiple d.f. effects for continuous variables that were not modeled through rcs, pol, lsp, etc., tests of linearity will be omitted. This applies to matrix predictors produced by e.g. poly or ns. `print.anova.rms` is the printing...
anova.rms draws dot charts depicting the importance of variables in the model, as measured by Wald $\chi^2$, $\chi^2$ minus d.f., AIC, $P$-values, partial $R^2$, $R^2$ for the whole model after deleting the effects in question, or proportion of overall model $R^2$ that is due to each predictor. latex.anova.rms is the latex method. It substitutes Greek/math symbols in column headings, uses boldface for TOTAL lines, and constructs a caption. Then it passes the result to latex.default for conversion to LaTeX.

For Bayesian models such as blrm, anova computes relative explained variation indexes (REV) based on approximate Wald statistics. This uses the variance-covariance matrix of all of the posterior draws, and the individual draws of betas, plus an overall summary from the posterior mode/mean/median beta. Wald chi-squares assuming multivariate normality of betas are computed just as with frequentist models, and for each draw (or for the summary) the ratio of the partial Wald chi-square to the total Wald statistic for the model is computed as REV.

The print method calls latex or html methods depending on options(prType=), and output is to the console. For latex a table environment is not used and an ordinary tabular is produced.

html.anova.rms just calls latex.anova.rms.

Usage

```r
## S3 method for class 'rms'
anova(object, ..., main.effect=FALSE, tol=1e-9, 
    test=c('F','Chisq'), india=TRUE, indnl=TRUE, ss=TRUE, 
    vnames=c('names','labels'),
    posterior.summary=c('mean', 'median', 'mode'), ns=500, cint=0.95)

## S3 method for class 'anova.rms'
print(x, 
    which=c('none','subscripts','names','dots'),
    table.env=FALSE, ...)

## S3 method for class 'anova.rms'
plot(x, 
    what=c("chisqminusdf","chisq","aic","P","partial R2","remaining R2", 
    "proportion R2", "proportion chisq"),
    xlab=NULL, pch=16, 
    rm.totals=TRUE, rm.ia=FALSE, rm.other=NULL, newnames, 
    sort=c("descending","ascending","none"), margin=c('chisq','P'), 
    pl=TRUE, trans=NULL, ntrans=40, height=NULL, width=NULL, ...)

## S3 method for class 'anova.rms'
latex(object, title, dec.chisq=2, 
    dec.F=2, dec.ss=NA, dec.ms=NA, dec.P=4, dec.REV=3, table.env=TRUE, 
    caption=NULL, ...)

## S3 method for class 'anova.rms'
html(object, ...)
```
Arguments

object

a rms fit object. object must allow vcov to return the variance-covariance matrix. For latex is the result of anova.

If omitted, all variables are tested, yielding tests for individual factors and for pooled effects. Specify a subset of the variables to obtain tests for only those factors, with a pooled Wald tests for the combined effects of all factors listed. Names may be abbreviated. For example, specify anova(fit, age, cholesterol) to get a Wald statistic for testing the joint importance of age, cholesterol, and any factor interacting with them.

Can be optional graphical parameters to send to dotchart2, or other parameters to send to latex.default. Ignored for print.

For html.anova.rms the arguments are passed to latex.anova.rms.

main.effect

Set to TRUE to print the (usually meaningless) main effect tests even when the factor is involved in an interaction. The default is FALSE, to print only the effect of the main effect combined with all interactions involving that factor.

tol

singularity criterion for use in matrix inversion

test

For an ols fit, set test="Chisq" to use Wald $\chi^2$ tests rather than F-tests.

india

set to FALSE to exclude individual tests of interaction from the table

indnl

set to FALSE to exclude individual tests of nonlinearity from the table

ss

For an ols fit, set ss=FALSE to suppress printing partial sums of squares, mean squares, and the Error SS and MS.

vnames

set to 'labels' to use variable labels rather than variable names in the output

posterior.summary

specifies whether the posterior mode/mean/median beta are to be used as a measure of central tendency of the posterior distribution, for use in relative explained variation from Bayesian models

ns

number of random samples from the posterior draws to use for REV highest posterior density intervals

cint

HPD interval probability

x

for print,plot,text is the result of anova.

which

If which is not "none" (the default), print.anova.rms will add to the rightmost column of the output the list of parameters being tested by the hypothesis being tested in the current row. Specifying which="subscripts" causes the subscripts of the regression coefficients being tested to be printed (with a subscript of one for the first non-intercept term). which="names" prints the names of the terms being tested, and which="dots" prints dots for terms being tested and blanks for those just being adjusted for.

what

what type of statistic to plot. The default is the Wald $\chi^2$ statistic for each factor (adding in the effect of higher-ordered factors containing that factor) minus its degrees of freedom. The R2 choices for what only apply to ols models.

xlab

x-axis label, default is constructed according to what. plotmath symbols are used for R, by default.

pch

character for plotting dots in dot charts. Default is 16 (solid dot).
**Details**

If the statistics being plotted with `plot.anova.rms` are few in number and one of them is negative or zero, `plot.anova.rms` will quit because of an error in `dotchart2`.

The `latex` method requires LaTeX packages `relsize` and `needspace`.

---

**Arguments**

- `rm.totals`: set to FALSE to keep total $\chi^2$s (overall, nonlinear, interaction totals) in the chart.
- `rm.ia`: set to TRUE to omit any effect that has "*" in its name.
- `rm.other`: a list of other predictor names to omit from the chart.
- `newnames`: a list of substitute predictor names to use, after omitting any.
- `sort`: default is to sort bars in descending order of the summary statistic.
- `margin`: set to a vector of character strings to write for selected statistics in the right margin of the dot chart. The character strings can be any combination of "chisq", "d.f.", "P", "partial R2", "proportion R2", and "proportion chisq". Default is to not draw any statistics in the margin. When `plotly` is in effect, margin values are instead displayed as hover text.
- `pl`: set to FALSE to suppress plotting. This is useful when you only wish to analyze the vector of statistics returned.
- `trans`: set to a function to apply that transformation to the statistics being plotted, and to truncate negative values at zero. A good choice is `trans=sqrt`.
- `ntrans`: an argument to `pretty`, specifying the number of values for which to place tick marks. This should be larger than usual because of nonlinear scaling, to provide a sufficient number of tick marks on the left (stretched) part of the chi-square scale.
- `height,width`: height and width of `plotly` plots drawn using `dotchartp`, in pixels. Ignored for ordinary plots. Defaults to minimum of 400 and 100 + 25 times the number of test statistics displayed.
- `title`: title to pass to `latex`, default is name of fit object passed to `anova` prefixed with "anova.". For Windows, the default is "ano" followed by the first 5 letters of the name of the fit object.
- `dec.chisq`: number of places to the right of the decimal place for typesetting $\chi^2$ values (default is 2). Use zero for integer, NA for floating point.
- `dec.F`: digits to the right for F statistics (default is 2)
- `dec.ss`: digits to the right for sums of squares (default is NA, indicating floating point)
- `dec.ms`: digits to the right for mean squares (default is NA)
- `dec.P`: digits to the right for P-values
- `dec.REV`: digits to the right for REV
- `table.env`: see `latex`
- `caption`: caption for table if `table.env` is TRUE. Default is constructed from the response variable.
Value

anova.rms returns a matrix of class anova.rms containing factors as rows and $\chi^2$, d.f., and $P$-values as columns (or d.f., partial SS, MS, F, P). An attribute vinfo provides list of variables involved in each row and the type of test done. plot.anova.rms invisibly returns the vector of quantities plotted. This vector has a names attribute describing the terms for which the statistics in the vector are calculated.

Side Effects

print prints, latex creates a file with a name of the form "title.tex" (see the title argument above).

    geom_errorbar(aes(ymin=lim[,1], ymax=lim[,2]), width=0)

$bj$ **Buckley-James Multiple Regression Model**

**Description**

bj fits the Buckley-James distribution-free least squares multiple regression model to a possibly right-censored response variable. This model reduces to ordinary least squares if there is no censoring. By default, model fitting is done after taking logs of the response variable. bj uses the rms class for automatic anova, fastbw, validate, Function, nomogram, summary, plot, bootcov, and other functions. The bootcov function may be worth using with bj fits, as the properties of the Buckley-James covariance matrix estimator are not fully known for strange censoring patterns.

For the print method, format of output is controlled by the user previously running options(prType="lang") where lang is "plain" (the default), "latex", or "html".

The residuals bj function exists mainly to compute residuals and to censor them (i.e., return them as Surv objects) just as the original failure time variable was censored. These residuals are useful for checking to see if the model also satisfies certain distributional assumptions. To get these residuals, the fit must have specified y=TRUE.

The bjplot function is a special plotting function for objects created by bj with x=TRUE, y=TRUE in effect. It produces three scatterplots for every covariate in the model: the first plots the original situation, where censored data are distinguished from non-censored data by a different plotting symbol. In the second plot, called a renovated plot, vertical lines show how censored data were changed by the procedure, and the third is equal to the second, but without vertical lines. Imputed data are again distinguished from the non-censored by a different symbol.

The validate method for bj validates the Somers’ Dxy rank correlation between predicted and observed responses, accounting for censoring.

The primary fitting function for bj is bj.fit, which does not allow missing data and expects a full design matrix as input.

**Usage**

```
bj(formula, data=environment(formula), subset, na.action=na.delete, 
link="log", control, method='fit', x=FALSE, y=FALSE, 
```
time.inc)

## S3 method for class 'bj'
print(x, digits=4, long=FALSE, coefs=TRUE,
title="Buckley-James Censored Data Regression", ...)

## S3 method for class 'bj'
residuals(object, type=c("censored","censored.normalized"),...)

bjplot(fit, which=1:dim(X)[[2]])

## S3 method for class 'bj'
validate(fit, method="boot", B=40,
    bw=FALSE,rule="aic",type="residual",sls=.05,aics=0,
    force=NULL, estimates=TRUE, pr=FALSE,
    tol=1e-7, rel.tolerance=1e-3, maxiter=15, ...)

bj.fit(x, y, control)

Arguments

formula         an S statistical model formula. Interactions up to third order are supported. The
left hand side must be a Surv object.
data,subset,na.action
    the usual statistical model fitting arguments
fit              a fit created by bj, required for all functions except bj.
x
    a design matrix with or without a first column of ones, to pass to bj.fit. All
    models will have an intercept. For print.bj is a result of bj. For bj, set x=TRUE
    to include the design matrix in the fit object.
y
    a Surv object to pass to bj.fit as the two-column response variable. Only right
    censoring is allowed, and there need not be any censoring. For bj, set y to TRUE
    to include the two-column response matrix, with the event/censoring indicator
    in the second column. The first column will be transformed according to link,
    and depending on na.action, rows with missing data in the predictors or the
    response will be deleted.
link
    set to, for example, "log" (the default) to model the log of the response, or
    "identity" to model the untransformed response.
control
    a list containing any or all of the following components: iter.max (maximum
    number of iterations allowed, default is 20), eps (convergence criterion: concer-
    gence is assumed when the ratio of sum of squared errors from one iteration to
    the next is between 1-eps and 1+eps), trace (set to TRUE to monitor iterations),
    tol (matrix singularity criterion, default is 1e-7), and 'max.cycle' (in case of
    nonconvergence the program looks for a cycle that repeats itself, default is 30).
method
    set to "model.frame" or "model.matrix" to return one of those objects rather
    than the model fit.
time.inc
    setting for default time spacing. Default is 30 if time variable has units="Day",
    I otherwise, unless maximum follow-up time < 1. Then max time/10 is used
as `time.inc`. If `time.inc` is not given and `max.time/default time.inc` is > 25, `time.inc` is increased.

**digits**
number of significant digits to print if not 4.

**long**
set to `TRUE` to print the correlation matrix for parameter estimates

**coefs**
specify `coefs=FALSE` to suppress printing the table of model coefficients, standard errors, etc. Specify `coefs=n` to print only the first `n` regression coefficients in the model.

**title**
a character string title to be passed to `prModFit`

**object**
the result of `bj`

**type**
type of residual desired. Default is censored unnormalized residuals, defined as \( \text{link}(Y) - \text{linear.predictors} \), where the link function was usually the log function. You can specify `type=\"censored.normalized\"` to divide the residuals by the estimate of `sigma`.

**which**
vector of integers or character strings naming elements of the design matrix (the names of the original predictors if they entered the model linearly) for which to have `bjplot` make plots of only the variables listed in which (names or numbers).

`B,bw,rule,sls,aics,force,estimates,pr,tol,rel.tolerance,maxiter`
see `predab.resample`

... ignored for print; passed through to `predab.resample` for `validate`

### Details

The program implements the algorithm as described in the original article by Buckley & James. Also, we have used the original Buckley & James prescription for computing variance/covariance estimator. This is based on non-censored observations only and does not have any theoretical justification, but has been shown in simulation studies to behave well. Our experience confirms this view. Convergence is rather slow with this method, so you may want to increase the number of iterations. Our experience shows that often, in particular with high censoring, 100 iterations is not too many. Sometimes the method will not converge, but will instead enter a loop of repeating values (this is due to the discrete nature of Kaplan and Meier estimator and usually happens with small sample sizes). The program will look for such a loop and return the average betas. It will also issue a warning message and give the size of the cycle (usually less than 6).

### Value

`bj` returns a fit object with similar information to what `survreg`, `psm`, `cph` would store as well as what `rms` stores and `units` and `time.inc` residuals. `bj` returns a `Surv` object. One of the components of the fit object produced by `bj` (and `bj.fit`) is a vector called `stats` which contains the following names elements: "obs", "Events", "d.f.", "error d.f.", "sigma", "g". Here `sigma` is the estimate of the residual standard deviation. `g` is the `g`-index. If the link function is "log", the `g`-index on the anti-log scale is also returned as `gr`.

bootBCa

BCa Bootstrap on Existing Bootstrap Replicates

Description

This function constructs an object resembling one produced by the boot package’s boot function, and runs that package’s boot.ci function to compute BCa and percentile confidence limits. bootBCa can provide separate confidence limits for a vector of statistics when estimate has length greater than 1. In that case, estimates must have the same number of columns as estimate has values.

Usage

bootBCa(estimate, estimates, type = c("percentile", "bca", "basic"), n, seed, conf.int = 0.95)

Arguments

estimate original whole-sample estimate
estimates vector of bootstrap estimates
type type of confidence interval, defaulting to nonparametric percentile
n original number of observations
seed .Random.seed in effect before bootstrap estimates were run
conf.int confidence level

Value

a 2-vector if estimate is of length 1, otherwise a matrix with 2 rows and number of columns equal to the length of estimate
Note
You can use `if(!exists('.Random.seed')) runif(1)` before running your bootstrap to make sure that `.Random.seed` will be available to `bootBCa`.

**bootcov**

*Bootstrap Covariance and Distribution for Regression Coefficients*

**Description**

`bootcov` computes a bootstrap estimate of the covariance matrix for a set of regression coefficients from `ols`, `lrm`, `cph`, `psm`, `Rq`, and any other fit where `x=TRUE, y=TRUE` was used to store the data used in making the original regression fit and where an appropriate fitter function is provided here. The estimates obtained are not conditional on the design matrix, but are instead unconditional estimates. For small sample sizes, this will make a difference as the unconditional variance estimates are larger. This function will also obtain bootstrap estimates corrected for cluster sampling (intra-cluster correlations) when a “working independence” model was used to fit data which were correlated within clusters. This is done by substituting cluster sampling with replacement for the usual simple sampling with replacement. `bootcov` has an option (`coef.reps`) that causes all of the regression coefficient estimates from all of the bootstrap re-samples to be saved, facilitating computation of nonparametric bootstrap confidence limits and plotting of the distributions of the coefficient estimates (using histograms and kernel smoothing estimates).

The `loglik` option facilitates the calculation of simultaneous confidence regions from quantities of interest that are functions of the regression coefficients, using the method of Tibshirani(1996).
With Tibshirani’s method, one computes the objective criterion (-2 log likelihood evaluated at the bootstrap estimate of $\beta$ but with respect to the original design matrix and response vector) for the original fit as well as for all of the bootstrap fits. The confidence set of the regression coefficients is the set of all coefficients that are associated with objective function values that are less than or equal to say the 0.95 quantile of the vector of $B + 1$ objective function values. For the coefficients satisfying this condition, predicted values are computed at a user-specified design matrix $X$, and minima and maxima of these predicted values (over the qualifying bootstrap repetitions) are computed to derive the final simultaneous confidence band.

The bootplot function takes the output of bootcov and either plots a histogram and kernel density estimate of specified regression coefficients (or linear combinations of them through the use of a specified design matrix $X$), or a qqnorm plot of the quantities of interest to check for normality of the maximum likelihood estimates. bootplot draws vertical lines at specified quantiles of the bootstrap distribution, and returns these quantiles for possible printing by the user. Bootstrap estimates may optionally be transformed by a user-specified function fun before plotting.

The confplot function also uses the output of bootcov but to compute and optionally plot non-parametric bootstrap pointwise confidence limits or (by default) Tibshirani (1996) simultaneous confidence sets. A design matrix must be specified to allow confplot to compute quantities of interest such as predicted values across a range of values or differences in predicted values (plots of effects of changing one or more predictor variable values).

bootplot and confplot are actually generic functions, with the particular functions bootplot.bootcov and confplot.bootcov automatically invoked for bootcov objects.

A service function called histdensity is also provided (for use with bootplot). It runs hist and density on the same plot, using twice the number of classes than the default for hist, and 1.5 times the width than the default used by density.

A comprehensive example demonstrates the use of all of the functions.

Usage

```r
bootcov(fit, cluster, B=200, fitter, 
  coef.reps=TRUE, loglik=FALSE, 
  pr=FALSE, maxit=15, eps=0.0001, group=NULL, stat=NULL)

bootplot(obj, which=1:ncol(Coef), X, 
  conf.int=c(.9,.95,.99), 
  what=c('density', 'qqnorm', 'box'), 
  fun=function(x) x, labels., ...)

confplot(obj, X, against, 
  method=c('simultaneous','pointwise'), 
  conf.int=0.95, fun=function(x)x, 
  add=FALSE, lty.conf=2, ...)

histdensity(y, xlab, nclass, width, mult.width=1, ...)
```
Arguments

fit a fit object containing components x and y. For fits from cph, the "strata" attribute of the x component is used to obtain the vector of stratum codes.

obj an object created by bootcov with coef.reps=TRUE.

X a design matrix specified to confplot. See predict.rms or contrast.rms. For bootplot, X is optional.

y a vector to pass to histdensity. NAs are ignored.

cluster a variable indicating groupings. cluster may be any type of vector (factor, character, integer). Unique values of cluster indicate possibly correlated groupings of observations. Note the data used in the fit and stored in fit$x and fit$y may have had observations containing missing values deleted. It is assumed that if there were any NAs, an naresid function exists for the class of fit. This function restores NAs so that the rows of the design matrix coincide with cluster.

B number of bootstrap repetitions. Default is 200.

fitter the name of a function with arguments (x,y) that will fit bootstrap samples. Default is taken from the class of fit if it is ols, lrm, cph, psm, Rq.

coef.reps set to TRUE if you want to store a matrix of all bootstrap regression coefficient estimates in the returned component boot.Cof.

loglik set to TRUE to store -2 log likelihoods for each bootstrap model, evaluated against the original x and y data. The default is to do this when coef.reps is specified as TRUE. The use of loglik=TRUE assumes that an oos.loglik method exists for the type of model being analyzed, to calculate out-of-sample -2 log likelihoods (see rmsMisc). After the B -2 log likelihoods (stored in the element named boot.loglik in the returned fit object), the B+1 element is the -2 log likelihood for the original model fit.

pr set to TRUE to print the current sample number to monitor progress.

maxit maximum number of iterations, to pass to fitter

eps argument to pass to various fitters

group a grouping variable used to stratify the sample upon bootstrapping. This allows one to handle k-sample problems, i.e., each bootstrap sample will be forced to select the same number of observations from each level of group as the number appearing in the original dataset. You may specify both group and cluster.

stat a single character string specifying the name of a stats element produced by the fitting function to save over the bootstrap repetitions. The vector of saved statistics will be in the boot.stats part of the list returned by bootcov.

which one or more integers specifying which regression coefficients to plot for bootplot

conf.int a vector (for bootplot, default is c(.9,.95,.99)) or scalar (for confplot, default is .95) confidence level.

what for bootplot, specifies whether a density or a q-q plot is made, a ggplot2 is used to produce a box plot of all coefficients over the bootstrap reps

fun for bootplot or confplot specifies a function used to translate the quantities of interest before analysis. A common choice is fun=exp to compute anti-logs, e.g., odds ratios.
labels. a vector of labels for labeling the axes in plots produced by bootplot. Default is row names of X if there are any, or sequential integers.

... For bootplot these are optional arguments passed to histdensity. Also may be optional arguments passed to plot by confplot or optional arguments passed to hist from histdensity, such as xlim and breaks. The argument probability=TRUE is always passed to hist.

against For confplot, specifying against causes a plot to be made (or added to). The against variable is associated with rows of X and is used as the x-coordinates.

method specifies whether "pointwise" or "simultaneous" confidence regions are derived by confplot. The default is simultaneous.

add set to TRUE to add to an existing plot, for confplot

lty.conf line type for plotting confidence bands in confplot. Default is 2 for dotted lines.

xlab label for x-axis for histdensity. Default is label attribute or argument name if there is no label.

nclass passed to hist if present

width passed to density if present

mult.width multiplier by which to adjust the default width passed to density. Default is 1.

Details

If the fit has a scale parameter (e.g., a fit from psm), the log of the individual bootstrap scale estimates are added to the vector of parameter estimates and and column and row for the log scale are added to the new covariance matrix (the old covariance matrix also has this row and column).

For Rq fits, the tau, method, and hs arguments are taken from the original fit.

Value

a new fit object with class of the original object and with the element orig.var added. orig.var is the covariance matrix of the original fit. Also, the original var component is replaced with the new bootstrap estimates. The component boot.coef is also added. This contains the mean bootstrap estimates of regression coefficients (with a log scale element added if applicable). boot.Coef is added if coef.reps=TRUE. boot.loglik is added if loglik=TRUE. If stat is specified an additional vector boot.stats will be contained in the returned object. B contains the number of successfully fitted bootstrap resamples. A component clusterInfo is added to contain elements name and n holding the name of the cluster variable and the number of clusters.

bootplot returns a (possible matrix) of quantities of interest and the requested quantiles of them.

confplot returns three vectors: fitted, lower, and upper.

Side Effects

bootcov prints if pr=TRUE

## End(Not run)
Description

Uses lattice graphics and the output from Predict to plot image, contour, or perspective plots showing the simultaneous effects of two continuous predictor variables. Unless formula is provided, the x-axis is constructed from the first variable listed in the call to Predict and the y-axis variable comes from the second.

The perimeter function is used to generate the boundary of data to plot when a 3-d plot is made. It finds the area where there are sufficient data to generate believable interaction fits.

Usage

\[ \text{bplot}(x, \text{formula}, \text{lfun}=\text{lattice::levelplot}, \text{xlab}, \text{ylab}, \text{zlab}, \text{adj.subtitle}=!\text{info$ref.zero}, \text{cex.adj}=.75, \text{cex.lab}=1, \text{perim}, \text{showperim}=\text{FALSE}, \text{zlim}=\text{range}(\text{yhat, na.rm=TRUE}), \text{scales}=\text{list(arrows=FALSE)}, \text{xlabrot}, \text{ylabrot}, \text{zlabrot}=90, \ldots) \]

\[ \text{perimeter}(x, y, \text{xinc}=(\text{diff(range(x)}))/10, \text{n}=10, \text{lowess=}\text{TRUE}) \]

Arguments

\( x \) for \text{bplot}, an object created by \text{Predict} for which two or more numeric predictors varied. For \text{perim} is the first variable of a pair of predictors forming a 3-d plot.

\( \text{formula} \) a formula of the form \( f(\text{yhat}) \sim x*y \) optionally followed by \( a*b*c \) which are 1-3 paneling variables that were specified to \text{Predict}. \( f \) can represent any \text{R} function of a vector that produces a vector. If the left hand side of the formula is omitted, \text{yhat} will be inserted. If \text{formula} is omitted, it will be inferred from the first two variables that varied in the call to \text{Predict}.

\( \text{lfun} \) a high-level lattice plotting function that takes formulas of the form \( z \sim x*y \). The default is an image plot (\text{levelplot}). Other common choices are \text{wireframe} for perspective plot or \text{contourplot} for a contour plot.

\( \text{xlab} \) Character string label for \( x \)-axis. Default is given by \text{Predict}.

\( \text{ylab} \) Character string \( y \)-axis label.

\( \text{zlab} \) Character string \( z \)-axis label for perspective (wireframe) plots. Default comes from \text{Predict}. \text{zlab} will often be specified if \( \text{fun} \) was specified to \text{Predict}.

\( \text{adj.subtitle} \) Set to \text{FALSE} to suppress subtitling the graph with the list of settings of non-graphed adjustment values. Default is \text{TRUE} if there are non-plotted adjustment variables and \text{ref.zero} was not used.

\( \text{cex.adj} \) \text{cex} parameter for size of adjustment settings in subtitles. Default is 0.75

\( \text{cex.lab} \) \text{cex} parameter for axis labels. Default is 1.

\( \text{perim} \) names a matrix created by \text{perimeter} when used for 3-d plots of two continuous predictors. When the combination of variables is outside the range in \text{perim}, that section of the plot is suppressed. If \text{perim} is omitted, 3-d plotting will use the marginal distributions of the two predictors to determine the plotting region, when the grid is not specified explicitly in \text{variables}. When instead a series of
curves is being plotted, `perim` specifies a function having two arguments. The first is the vector of values of the first variable that is about to be plotted on the x-axis. The second argument is the single value of the variable representing different curves, for the current curve being plotted. The function’s returned value must be a logical vector whose length is the same as that of the first argument, with values `TRUE` if the corresponding point should be plotted for the current curve, `FALSE` otherwise. See one of the latter examples.

- `showperim`: set to `TRUE` if `perim` is specified and you want to show the actual perimeter used.
- `zlim`: Controls the range for plotting in the z-axis if there is one. Computed by default.
- `scales`: see `wireframe`
- `xlabrot`: rotation angle for the x-axis. Default is 30 for `wireframe` and 0 otherwise.
- `ylabrot`: rotation angle for the y-axis. Default is -40 for `wireframe`, 90 for `contourplot` or `levelplot`, and 0 otherwise.
- `zlabrot`: rotation angle for z-axis rotation for `wireframe` plots
- `...`: other arguments to pass to the lattice function
- `y`: second variable of the pair for `perim`. If omitted, x is assumed to be a list with both x and y components.
- `xinc`: increment in x over which to examine the density of y in `perimeter`
- `n`: within intervals of x for `perimeter`, takes the informative range of y to be the nth smallest to the nth largest values of y. If there aren’t at least 2n y values in the x interval, no y ranges are used for that interval.
- `lowess`: set to `FALSE` to not have `lowess` smooth the data perimeters

**Details**

`perimeter` is a kind of generalization of `datadist` for 2 continuous variables. First, the n smallest and largest x values are determined. These form the lowest and highest possible xs to display. Then x is grouped into intervals bounded by these two numbers, with the interval widths defined by `xinc`. Within each interval, y is sorted and the nth smallest and largest y are taken as the interval containing sufficient data density to plot interaction surfaces. The interval is ignored when there are insufficient y values. When the data are being readied for `persp`, `bplot` uses the `approx` function to do linear interpolation of the y-boundaries as a function of the x values actually used in forming the grid (the values of the first variable specified to `Predict`). To make the perimeter smooth, specify `lowess.=TRUE` to `perimeter`.

**Value**

`perimeter` returns a matrix of class `perimeter`. This outline can be conveniently plotted by `lines.perimeter`.

**calibrate**  
*Resampling Model Calibration*
Description

Uses bootstrapping or cross-validation to get bias-corrected (overfitting-corrected) estimates of predicted vs. observed values based on subsetting predictions into intervals (for survival models) or on nonparametric smoothers (for other models). There are calibration functions for Cox (cph), parametric survival models (psm), binary and ordinal logistic models (lrm) and ordinary least squares (ols). For survival models, "predicted" means predicted survival probability at a single time point, and "observed" refers to the corresponding Kaplan-Meier survival estimate, stratifying on intervals of predicted survival, or, if the polspline package is installed, the predicted survival probability as a function of transformed predicted survival probability using the flexible hazard regression approach (see the val.surv function for details). For logistic and linear models, a nonparametric calibration curve is estimated over a sequence of predicted values. The fit must have specified x=TRUE, y=TRUE. The print and plot methods for lrm and ols models (which use calibrate.default) print the mean absolute error in predictions, the mean squared error, and the 0.9 quantile of the absolute error. Here, error refers to the difference between the predicted values and the corresponding bias-corrected calibrated values.

Below, the second, third, and fourth invocations of calibrate are, respectively, for ols and lrm, cph, and psm. The first and second plot invocation are respectively for lrm and ols fits or all other fits.

Usage

calibrate(fit, ...)  
## Default S3 method:
calibrate(fit, predy,  
method=c("boot","crossvalidation",".632","randomization"),

Arguments

- **fit**: a fit from ols, lr, cph or psm
- **x**: an object created by calibrate
- **method, B, bw, rule, type, sls, aics, force, estimates**
  see validate. For print.calibrate, B is an upper limit on the number of
  resamples for which information is printed about which variables were selected
  in each model re-fit. Specify zero to suppress printing. Default is to print all
  re-samples.
- **cmethod**: method for validating survival predictions using right-censored data. The default
  is cmethod='hare' to use the hare function in the polsplines package. Specify
  cmethod='KM' to use less precision stratified Kaplan-Meier estimates. If the
  polsplines package is not available, the procedure reverts to cmethod='KM'.
- **u**: the time point for which to validate predictions for survival models. For
cph fits, you must have specified surv=TRUE, time.inc=u, where u is the constant
  specifying the time to predict.
- **m**: group predicted u-time units survival into intervals containing m subjects on the
  average (for survival models only)
- **pred**: vector of predicted survival probabilities at which to evaluate the calibration
  curve. By default, the low and high prediction values from datadist are used,
  which for large sample size is the 10th smallest to the 10th largest predicted
  probability.
- **cuts**: actual cut points for predicted survival probabilities. You may specify only one
  of m and cuts (for survival models only)
- **pr**: set to TRUE to print intermediate results for each re-sample
- **what**: The default is "observed-predicted", meaning to estimate optimism in this
  difference. This is preferred as it accounts for skewed distributions of predicted
  probabilities in outer intervals. You can also specify "observed". This argument
  applies to survival models only.
- **tol**: criterion for matrix singularity (default is 1e-12)
- **maxdim**: see hare
- **maxiter**: for psm, this is passed to survreg.control (default is 15 iterations)
- **rel.tolerance**: parameter passed to survreg.control for psm (default is 1e-5).
- **predy**: a scalar or vector of predicted values to calibrate (for lr, ols). Default is
  50 equally spaced points between the 5th smallest and the 5th largest predicted
  values. For lr the predicted values are probabilities (see kint).
For an ordinal logistic model the default predicted probability that $Y \geq$ the middle level. Specify `kint` to specify the intercept to use, e.g., `kint=2` means to calibrate $\text{Prob}(Y \geq b)$, where $b$ is the second level of $Y$.

A function in two variables which produces $x$- and $y$-coordinates by smoothing the input $y$. The default is to use `lowess(x, y, iter=0)`.

If specified, predicted values are rounded to `digits` digits before passing to the smoother. Occasionally, large predicted values on the logit scale will lead to predicted probabilities very near 1 that should be treated as 1, and the round function will fix that. Applies to `calibrate.default`.

Other arguments to pass to `predab.resample`, such as `group`, `cluster`, and `subset`. Also, other arguments for `plot`.

Defaults to "Predicted x-units Survival" or to a suitable label for other models

defaults to "Fraction Surviving x-units" or to a suitable label for other models

2-vectors specifying $x$- and $y$-axis limits, if not using defaults

set to FALSE to suppress subtitles in plot describing method and for `lrm` and `ols` the mean absolute error and original sample size

set to FALSE to suppress plotting 0.95 confidence intervals for Kaplan-Meier estimates

character size for plotting subtitles

set to FALSE to suppress the distribution of predicted risks (survival probabilities) from being plotted

set to TRUE to add the calibration plot to an existing plot

a list specifying options to send to `scat1d` if `riskdist=TRUE`. See `scat1d`.

a list specifying graphics parameters `col`, `lty`, `lwd`, `pch` to be used in drawing overfitting-corrected estimates. Default is `col="blue", lty=1, lwd=1, pch=4`.

set to FALSE to suppress legends (for `lrm`, `ols` only) on the calibration plot, or specify a list with elements `x` and `y` containing the coordinates of the upper left corner of the legend. By default, a legend will be drawn in the lower right 1/16th of the plot.

If the fit was created using penalized maximum likelihood estimation, the same `penalty` and `penalty.scale` parameters are used during validation.

matrix specifying mean predicted survival in each interval, the corresponding estimated bias-corrected Kaplan-Meier estimates, number of subjects, and other statistics. For linear and logistic models, the matrix instead has rows corresponding to the prediction points, and the vector of predicted values being validated is returned as an attribute. The returned object has class "calibrate" or "calibrate.default". `plot.calibrate.default` invisibly returns the vector of estimated prediction errors corresponding to the dataset used to fit the model.
Side Effects

prints, and stores an object \texttt{pred.obs} or \texttt{.orig.cal}

Examples

```r
set.seed(1)
n <- 200
d.time <- rexp(n)
x1 <- runif(n)
x2 <- factor(sample(c('a', 'b', 'c'), n, TRUE))
f <- cph(Surv(d.time) ~ pol(x1,2) * x2, x=TRUE, y=TRUE, surv=TRUE, time.inc=1.5)
# or f <- psm(S ~ \ldots)
if(pa) {
  cal <- calibrate(f, u=1.5, B=20)  # cmethod='hare'
  plot(cal)
}

set.seed(1)
y <- sample(0:2, n, TRUE)
x1 <- runif(n)
x2 <- runif(n)
x3 <- runif(n)
x4 <- runif(n)
f <- lrm(y ~ x1 + x2 + x3 * x4, x=TRUE, y=TRUE)

# group= does k-sample validation: make resamples have same
# numbers of subjects in each level of y as original sample

plot(cal)
```

See the example for the validate function for a method of validating
continuation ratio ordinal logistic models. You can do the same
thing for calibrate
**contrast.rms**

**General Contrasts of Regression Coefficients**

**Description**

This function computes one or more contrasts of the estimated regression coefficients in a fit from one of the functions in rms, along with standard errors, confidence limits, t or Z statistics, P-values. General contrasts are handled by obtaining the design matrix for two sets of predictor settings (a, b) and subtracting the corresponding rows of the two design matrices to obtain a new contrast design matrix for testing the a - b differences. This allows for quite general contrasts (e.g., estimated differences in means between a 30 year old female and a 40 year old male). This can also be used to obtain a series of contrasts in the presence of interactions (e.g., female:male log odds ratios for several ages when the model contains age by sex interaction). Another use of contrast is to obtain center-weighted (Type III test) and subject-weighted (Type II test) estimates in a model containing treatment by center interactions. For the latter case, you can specify type="average" and an optional weights vector to average the within-center treatment contrasts. The design contrast matrix computed by contrast.rms can be used by other functions.

When the model was fitted by a Bayesian function such as blrm, highest posterior density intervals for contrasts are computed instead, along with the posterior probability that the contrast is positive. posterior.summary specifies whether posterior mean/median/mode is to be used for contrast point estimates.

contrast.rms also allows one to specify four settings to contrast, yielding contrasts that are double differences - the difference between the first two settings (a - b) and the last two (a2 - b2). This allows assessment of interactions.

If usebootcoef=TRUE, the fit was run through bootcov, and conf.type="individual", the confidence intervals are bootstrap nonparametric percentile confidence intervals, basic bootstrap, or BCa intervals, obtained on contrasts evaluated on all bootstrap samples.

By omitting the b argument, contrast can be used to obtain an average or weighted average of a series of predicted values, along with a confidence interval for this average. This can be useful for "unconditioning" on one of the predictors (see the next to last example).

Specifying type="joint", and specifying at least as many contrasts as needed to span the space of a complex test, one can make multiple degree of freedom tests flexibly and simply. Redundant contrasts will be ignored in the joint test. See the examples below. These include an example of an "incomplete interaction test" involving only two of three levels of a categorical variable (the test also tests the main effect).

When more than one contrast is computed, the list created by contrast.rms is suitable for plotting (with error bars or bands) with xYplot or Dotplot (see the last example before the type="joint" examples).

When fit is the result of a Bayesian model fit and fun is specified, contrast.rms operates altogether differently. a and b must both be specified and a2, b2 not specified. fun is evaluated on the estimates separately on a and b and the subtraction is deferred. So even in the absence of interactions, when fun is nonlinear, the settings of factors (predictors) will not cancel out and estimates of differences will be covariate-specific (unless there are no covariates in the model besides the one being varied to get from a to b).
### Usage

```r
contrast(fit, ...)  # S3 method for class 'rms'
contrast(fit, a, b, a2, b2, ycut=NULL, cnames=NULL,  
         fun=NULL, funint=TRUE,  
         type=c("individual", "average", "joint"),  
         conf.type=c("individual", "simultaneous"), usebootcoef=TRUE,  
         boot.type=c("percentile", "bca", "basic"),  
         posterior.summary=c("mean", "median", "mode"),  
         weights="equal", conf.int=0.95, tol=1e-7, expand=TRUE, ...)
```

```r
# S3 method for class 'contrast.rms'
print(x, X=FALSE,  
      fun=function(u)u, jointonly=FALSE, prob=0.95, ...)
```

### Arguments

- **fit**
  - A fit of class "rms"

- **a**
  - A list containing settings for all predictors that you do not wish to set to default (adjust-to) values. Usually you will specify two variables in this list, one set to a constant and one to a sequence of values, to obtain contrasts for the sequence of values of an interacting factor. The `gendata` function will generate the necessary combinations and default values for unspecified predictors, depending on the `expand` argument.

- **b**
  - Another list that generates the same number of observations as `a`, unless one of the two lists generates only one observation. In that case, the design matrix generated from the shorter list will have its rows replicated so that the contrasts assess several differences against the one set of predictor values. This is useful for comparing multiple treatments with control, for example. If `b` is missing, the design matrix generated from `a` is analyzed alone.

- **a2**
  - An optional third list of settings of predictors

- **b2**
  - An optional fourth list of settings of predictors. Mandatory if `a2` is given.

- **ycut**
  - Used of the fit is a constrained partial proportional odds model fit, to specify the single value or vector of values (corresponding to the multiple contrasts) of the response variable to use in forming contrasts. When there is non-proportional odds, odds ratios will vary over levels of the response variable. When there are multiple contrasts and only one value is given for `ycut`, that value will be propagated to all contrasts. To show the effect of non-proportional odds, let `ycut` vary.

- **cnames**
  - A vector of character strings naming the contrasts when `type`!="average". Usually `cnames` is not necessary as `contrast.rms` tries to name the contrasts by examining which predictors are varying consistently in the two lists. `cnames` will be needed when you contrast "non-comparable" settings, e.g., you compare `list(treat="drug", age=c(20,30))` with `list(treat="placebo", age=c(40,50))`.

- **fun**
  - A function to evaluate on the linear predictor for each of `a` and `b`. Applies to Bayesian model fits. Also, a function to transform the contrast, SE, and lower
and upper confidence limits before printing. For example, specify fun=exp to anti-log them for logistic models.

type
set type="average" to average the individual contrasts (e.g., to obtain a Type II or III contrast). Set type="joint" to jointly test all non-redundant contrasts with a multiple degree of freedom test and no averaging.

conf.type The default type of confidence interval computed for a given individual (1 d.f.) contrast is a pointwise confidence interval. Set conf.type="simultaneous" to use the multcomp package's glht and confint functions to compute confidence intervals with simultaneous (family-wise) coverage, thus adjusting for multiple comparisons. Note that individual P-values are not adjusted for multiplicity.

usebootcoef If fit was the result of bootcov but you want to use the bootstrap covariance matrix instead of the nonparametric percentile, basic, or BCa method for confidence intervals (which uses all the bootstrap coefficients), specify usebootcoef=FALSE.

boot.type set to 'bca' to compute BCa confidence limits or 'basic' to use the basic bootstrap. The default is to compute percentile intervals

posterior.summary By default the posterior mean is used. Specify posterior.summary='median' to instead use the posterior median and likewise posterior.summary='mode'. Unlike other functions, contrast.rms does not default to 'mode' because point estimates come from contrasts and not the original model coefficients point estimates.

weights a numeric vector, used when type="average", to obtain weighted contrasts

conf.int confidence level for confidence intervals for the contrasts (HPD interval probability for Bayesian analyses)

tol tolerance for qr function for determining which contrasts are redundant, and for inverting the covariance matrix involved in a joint test

expand set to FALSE to have gendata not generate all possible combinations of predictor settings. This is useful when getting contrasts over irregular predictor settings.

... passed to print for main output. A useful thing to pass is digits=4.

x result of contrast

X set X=TRUE to print design matrix used in computing the contrasts (or the average contrast)

funint set to FALSE if fun is not a function such as the result of Mean, Quantile, or ExProb that contains an intercepts argument

jointonly set to FALSE to omit printing of individual contrasts

prob highest posterior density interval probability when the fit was Bayesian and fun was specified to contrast.rms

Value

a list of class "contrast.rms" containing the elements Contrast, SE, Z, var, df.residual Lower, Upper, Pvalue, X, cnames, redundant, which denote the contrast estimates, standard errors, Z or t-statistics, variance matrix, residual degrees of freedom (this is NULL if the model was not ols), lower and upper confidence limits, 2-sided P-value, design matrix, contrast names (or NULL), and
a logical vector denoting which contrasts are redundant with the other contrasts. If there are any redundant contrasts, when the results of contrast are printed, and asterisk is printed at the start of the corresponding lines. The object also contains ctype indicating what method was used for compute confidence intervals.

# Note: If using a spline fit, there should be at least one value of x1 between any two knots and beyond the outer knots.
options(datadist=NULL)
formula an S formula object with a Surv object on the left-hand side. The terms can specify any S model formula with up to third-order interactions. The strat function may appear in the terms, as a main effect or an interacting factor. To stratify on both race and sex, you would include both terms strat(race) and strat(sex). Stratification factors may interact with non-stratification factors; not all stratification terms need interact with the same modeled factors.

object an object created by cph with surv=TRUE

data name of an S data frame containing all needed variables. Omit this to use a data frame already in the S "search list".

weights case weights

subset an expression defining a subset of the observations to use in the fit. The default is to use all observations. Specify for example age>50 & sex="male" or c(1:100,200:300) respectively to use the observations satisfying a logical expression or those having row numbers in the given vector.

na.action specifies an S function to handle missing data. The default is the function na.delete, which causes observations with any variable missing to be deleted. The main difference between na.delete and the S-supplied function na.omit is that na.delete makes a list of the number of observations that are missing on each variable in the model. The na.action is usually specified by e.g. options(na.action="na.delete").

method for cph, specifies a particular fitting method, "model.frame" instead to return the model frame of the predictor and response variables satisfying any subset or missing value checks, or "model.matrix" to return the expanded design matrix. The default is "efron", to use Efron's likelihood for fitting the model.
For `Mean.cph`, method is "exact" to use numerical integration of the survival function at any linear predictor value to obtain a mean survival time. Specify method="approximate" to use an approximate method that is slower when `Mean.cph` is executing but then is essentially instant thereafter. For the approximate method, the area is computed for \( n \) points equally spaced between the min and max observed linear predictor values. This calculation is done separately for each stratum. Then the \( n \) pairs (X beta, area) are saved in the generated S function, and when this function is evaluated, the approx function is used to evaluate the mean for any given linear predictor values, using linear interpolation over the \( n \) X beta values.

`singular.ok` If TRUE, the program will automatically skip over columns of the X matrix that are linear combinations of earlier columns. In this case the coefficients for such columns will be NA, and the variance matrix will contain zeros. For ancillary calculations, such as the linear predictor, the missing coefficients are treated as zeros. The singularities will prevent many of the features of the `rms` library from working.

`robust` if TRUE a robust variance estimate is returned. Default is TRUE if the model includes a cluster() operative, FALSE otherwise.

`model` default is FALSE(false). Set to TRUE to return the model frame as element model of the fit object.

`x` default is FALSE. Set to TRUE to return the expanded design matrix as element x (without intercept indicators) of the returned fit object.

`y` default is FALSE. Set to TRUE to return the vector of response values (Surv object) as element y of the fit.

`se.fit` default is FALSE. Set to TRUE to compute the estimated standard errors of the estimate of X beta and store them in element se.fit of the fit. The predictors are first centered to their means before computing the standard errors.

`linear.predictors` set to FALSE to omit linear.predictors vector from fit

`residuals` set to FALSE to omit residuals vector from fit

`nonames` set to TRUE to not set names attribute for linear.predictors, residuals, se.fit, and rows of design matrix

`eps` convergence criterion - change in log likelihood.

`init` vector of initial parameter estimates. Defaults to all zeros. Special residuals can be obtained by setting some elements of init to MLEs and others to zero and specifying iter.max=1.

`iter.max` maximum number of iterations to allow. Set to 0 to obtain certain null-model residuals.

`tol` tolerance for declaring singularity for matrix inversion (available only when survival5 or later package is in effect)

`surv` set to TRUE to compute underlying survival estimates for each stratum, and to store these along with standard errors of log Lambda(t), maxtime (maximum observed survival or censoring time), and surv.summary in the returned object. Set surv="summary" to only compute and store surv.summary, not survival
estimates at each unique uncensored failure time. If you specify x=TRUE and y=TRUE, you can obtain predicted survival later, with accurate confidence intervals for any set of predictor values. The standard error information stored as a result of surv=TRUE are only accurate at the mean of all predictors. If the model has no covariables, these are of course OK. The main reason for using surv is to greatly speed up the computation of predicted survival probabilities as a function of the covariables, when accurate confidence intervals are not needed.

time.inc

time increment used in deriving surv.summary. Survival, number at risk, and standard error will be stored for t=0, time.inc, 2 time.inc, ..., maxtime, where maxtime is the maximum survival time over all strata. time.inc is also used in constructing the time axis in the survplot function (see below). The default value for time.inc is 30 if units(ftime) = "Day" or no units attribute has been attached to the survival time variable. If units(ftime) is a word other than "Day", the default for time.inc is 1 when it is omitted, unless maxtime<1, then maxtime/10 is used as time.inc. If time.inc is not given and maxtime default time.inc > 25, time.inc is increased.

type

(for cph) applies if surv is TRUE or "summary". If type is omitted, the method consistent with method is used. See survfit.coxph (under survfit) or survfit.cph for details and for the definitions of values of type

For Survival, Quantile, Mean set to "polygon" to use linear interpolation instead of the usual step function. For Mean, the default of step will yield the sample mean in the case of no censoring and no covariables, if type="kaplan-meier" was specified to cph. For method="exact", the value of type is passed to the generated function, and it can be overridden when that function is actually invoked. For method="approximate", Mean.cph generates the function different ways according to type, and this cannot be changed when the function is actually invoked.

vartype

see survfit.coxph

debug

set to TRUE to print debugging information related to model matrix construction. You can also use options(debug=TRUE).

... other arguments passed to coxph.fit from cph. Ignored by other functions.

times

a scalar or vector of times at which to evaluate the survival estimates

lp

a scalar or vector of linear predictors (including the centering constant) at which to evaluate the survival estimates

stratum

a scalar stratum number or name (e.g., "sex=male") to use in getting survival probabilities

q

a scalar quantile or a vector of quantiles to compute

n

the number of points at which to evaluate the mean survival time, for method="approximate" in Mean.cph.

tmax

For Mean.cph, the default is to compute the overall mean (and produce a warning message if there is censoring at the end of follow-up). To compute a restricted mean life length, specify the truncation point as tmax. For method="exact", tmax is passed to the generated function and it may be overridden when that function is invoked. For method="approximate", tmax must be specified at the time that Mean.cph is run.
Details

If there is any strata by covariable interaction in the model such that the mean X beta varies greatly over strata, method="approximate" may not yield very accurate estimates of the mean in Mean.cph.

For method="approximate" if you ask for an estimate of the mean for a linear predictor value that was outside the range of linear predictors stored with the fit, the mean for that observation will be NA.

Value

For Survival, Quantile, or Mean, an S function is returned. Otherwise, in addition to what is listed below, formula/design information and the components maxtime, time.inc, units, model, x, y, se.fit are stored, the last 5 depending on the settings of options by the same names. The vectors or matrix stored if y=TRUE or x=TRUE have rows deleted according to subset and to missing data, and have names or row names that come from the data frame used as input data.

n table with one row per stratum containing number of censored and uncensored observations
coeff vector of regression coefficients
stats vector containing the named elements Obs, Events, Model L.R., d.f., P, Score, Score P, R2, Somers' Dxy, g-index, and gr, the g-index on the hazard ratio scale.
R2 is the Nagelkerke R-squared, with division by the maximum attainable R-squared.
var variance/covariance matrix of coefficients
linear.predictors values of predicted X beta for observations used in fit, normalized to have overall mean zero, then having any offsets added
resid martingale residuals
loglik log likelihood at initial and final parameter values
score value of score statistic at initial values of parameters
times lists of times (if surv="T")
surv lists of underlying survival probability estimates
std.err lists of standard errors of estimate log-log survival
surv.summary a 3 dimensional array if surv=TRUE. The first dimension is time ranging from 0 to maxtime by time.inc. The second dimension refers to strata. The third dimension contains the time-oriented matrix with Survival, n.risk (number of subjects at risk), and std.err (standard error of log-log survival).
center centering constant, equal to overall mean of X beta.

**cr.setup**

**Continuation Ratio Ordinal Logistic Setup**

**Description**

Creates several new variables which help set up a dataset with an ordinal response variable \( y \) for use in fitting a forward continuation ratio (CR) model. The CR model can be fitted with binary logistic regression if each input observation is replicated the proper number of times according to the \( y \) value, a new binary \( y \) is computed that has at most one \( y = 1 \) per subject, and if a cohort variable is used to define the current qualifying condition for a cohort of subjects, e.g., \( y \geq 2 \). `cr.setup` creates the needed auxiliary variables. See `predab.resample` and `validate.lrm` for information about validating CR models (e.g., using the bootstrap to sample with replacement from the original subjects instead of the records used in the fit, validating the model separately for user-specified values of cohort).

**Usage**

```
cr.setup(y)
```

**Arguments**

- **y**: a character, numeric, category, or factor vector containing values of the response variable. For category or factor variables, the levels of the variable are assumed to be listed in an ordinal way.
Value

a list with components y, cohort, subs, reps. y is a new binary variable that is to be used in the binary logistic fit. cohort is a factor vector specifying which cohort condition currently applies. subs is a vector of subscripts that can be used to replicate other variables the same way y was replicated. reps specifies how many times each original observation was replicated. y, cohort, subs are all the same length and are longer than the original y vector. reps is the same length as the original y vector. The subs vector is suitable for passing to validate.lrm or calibrate, which pass this vector under the name cluster on to predab.resample so that bootstrapping can be done by sampling with replacement from the original subjects rather than from the individual records created by cr.setup.

cal <- calibrate(g, cluster=u$subs, subset=cohort=='all')
# subs makes bootstrap sample the correct units, subset causes
# Predicted Prob(pain.severity=0) to be checked for calibration

## End(Not run)
Description

For a given set of variables or a data frame, determines summaries of variables for effect and plotting ranges, values to adjust to, and overall ranges for Predict, plot.Predict, ggplot.Predict, summary.rms, survplot, and nomogram.rms. If datadist is called before a model fit and the resulting object pointed to with options(datadist="name"), the data characteristics will be stored with the fit by Design(), so that later predictions and summaries of the fit will not need to access the original data used in the fit. Alternatively, you can specify the values for each variable in the model when using these 3 functions, or specify the values of some of them and let the functions look up the remainder (of say adjustment levels) from an object created by datadist. The best method is probably to run datadist once before any models are fitted, storing the distribution summaries for all potential variables. Adjustment values are 0 for binary variables, the most frequent category (or optionally the first category level) for categorical (factor) variables, the middle level for ordered factor variables, and medians for continuous variables. See descriptions of q.display and q.effect for how display and effect ranges are chosen for continuous variables.

Usage

datadist(..., data, q.display, q.effect=c(0.25, 0.75),
          adjto.cat=c('mode','first'), n.unique=10)

## S3 method for class 'datadist'
print(x, ...)
# options(datadist="dd")
# used by summary, plot, survplot, sometimes predict
# For dd substitute the name of the result of datadist

Arguments

... a list of variable names, separated by commas, a single data frame, or a fit
with Design information. The first element in this list may also be an object
created by an earlier call to datadist; then the later variables are added
to this datadist object. For a fit object, the variables named in the fit are
retrieved from the active data frame or from the location pointed to by data=frame
number or data="data frame name". For print, is ignored.

data a data frame or a search position. If data is a search position, it is assumed that
a data frame is attached in that position, and all its variables are used. If you
specify both individual variables in ... and data, the two sets of variables are
combined. Unless the first argument is a fit object, data must be an integer.

q.display set of two quantiles for computing the range of continuous variables to use
in displaying regression relationships. Defaults are q and 1 – q, where q =
10/max(n,200), and n is the number of non-missing observations. Thus for
n < 200, the .05 and .95 quantiles are used. For n ≥ 200, the 10\textsuperscript{th} smallest and
10\textsuperscript{th} largest values are used. If you specify q.display, those quantiles are used
whether or not n < 200.

q.effect set of two quantiles for computing the range of continuous variables to use in estimating regression effects. Defaults are c(.25,.75), which yields inter-quartile-
range odds ratios, etc.
adjto.cat  default is "mode", indicating that the modal (most frequent) category for categorical (factor) variables is the adjust-to setting. Specify "first" to use the first level of factor variables as the adjustment values. In the case of many levels having the maximum frequency, the first such level is used for "mode".

n.unique  variables having n.unique or fewer unique values are considered to be discrete variables in that their unique values are stored in the values list. This will affect how functions such as nomogram.design determine whether variables are discrete or not.

x  result of datadist

Details

For categorical variables, the 7 limits are set to character strings (factors) which correspond to c(NA,adjto.level,NA,1,k,1,k), where k is the number of levels. For ordered variables with numeric levels, the limits are set to c(L,M,H,L,H,L,H), where L is the lowest level, M is the middle level, and H is the highest level.

Value

a list of class "datadist" with the following components

limits  a 7 x k vector, where k is the number of variables. The 7 rows correspond to the low value for estimating the effect of the variable, the value to adjust the variable to when examining other variables, the high value for effect, low value for displaying the variable, the high value for displaying it, and the overall lowest and highest values.

values  a named list, with one vector of unique values for each numeric variable having no more than n.unique unique values

d <- datadist(x1, x2, x3)  # if your options(pager) leaves up a pop-up
page(d)  # window, this is a useful guide in analyses
d <- datadist(data=2)  # all variables in search pos. 2
d <- datadist(data=my.data.frame)
d <- datadist(my.data.frame)  # same as previous. Run for all potential vars.
ExProb

Function Generator For Exceedance Probabilities

Description

For an `orm` object generates a function for computing the estimates of the function \( \text{Prob}(Y \geq y) \) given one or more values of the linear predictor using the reference (median) intercept. This function can optionally be evaluated at only a set of user-specified \( y \) values, otherwise a right-step function is returned. There is a plot method for plotting the step functions, and if more than one linear predictor was evaluated multiple step functions are drawn. `ExProb` is especially useful for `nomogram`.

Optionally a normal approximation for a confidence interval for exceedance probabilities will be computed using the delta method, if `conf.int > 0` is specified to the function generated from calling `ExProb`. In that case, a "lims" attribute is included in the result computed by the derived cumulative probability function.
Usage

ExProb(object, ...)

## S3 method for class 'orm'
ExProb(object, codes = FALSE, ...)

## S3 method for class 'ExProb'
plot(x, ..., data=NULL, 
    xlim=NULL, xlab=x$yname, ylab=expression(Prob(Y>=y)),
    col=par('col'), col.vert='gray85', pch=20,
    pch.data=21, lwd=par('lwd'), lwd.data=lwd,
    lty.data=2, key=TRUE)

Arguments

object        a fit object from `orm`
codes         if TRUE, ExProb use the integer codes 1, 2, ..., k for the k-level response instead of its original unique values
...           ignored for ExProb. Passed to plot for `plot.ExProb`
data          Specify data if you want to add stratified empirical probabilities to the graph. If data is a numeric vector, it is assumed that no groups are present. Otherwise data must be a list or data frame where the first variable is the grouping variable (corresponding to what made the linear predictor vary) and the second variable is the data vector for the y variable. The rows of data should be sorted to be in order of the linear predictor argument.
x        an object created by running the function created by ExProb
xlim         limits for x-axis; default is range of observed y
xlab         x-axis label
ylab         y-axis label
col          color for horizontal lines and points
col.vert     color for vertical discontinuities
pch          plotting symbol for predicted curves
lwd          line width for predicted curves
pch.data, lwd.data, lty.data
    plotting parameters for data
key          set to FALSE to suppress key in plot if data is given

Value

ExProb returns an R function. Running the function returns an object of class "ExProb".

**fastbw**

*Fast Backward Variable Selection*

**Description**

Performs a slightly inefficient but numerically stable version of fast backward elimination on factors, using a method based on Lawless and Singhal (1978). This method uses the fitted complete model and computes approximate Wald statistics by computing conditional (restricted) maximum likelihood estimates assuming multivariate normality of estimates. `fastbw` deletes factors, not columns of the design matrix. Factors requiring multiple d.f. will be retained or dropped as a group. The function prints the deletion statistics for each variable in turn, and prints approximate parameter estimates for the model after deleting variables. The approximation is better when the number of factors deleted is not large. For `ols`, the approximation is exact for regression coefficients, and standard errors are only off by a factor equal to the ratio of the mean squared error estimate for the reduced model to the original mean squared error estimate for the full model.

If the fit was from `ols`, `fastbw` will compute the usual $R^2$ statistic for each model.

**Usage**

```r
fastbw(fit, rule=c("aic", "p"),
       type=c("residual", "individual", "total"), sls=.05, aics=0, eps=1e-9,
       k.aic=2, force=NULL)
```

```r
## S3 method for class 'fastbw'
print(x, digits=4, estimates=TRUE, ...)
```
Arguments

- **fit**: fit object with `Varcov(fit)` defined (e.g., from `ols`, `lrm`, `cph`, `psn`, `glmD`)
- **rule**: Stopping rule. Defaults to "aic" for Akaike's information criterion. Use `rule="p"` to use \( P \)-values
- **type**: Type of statistic on which to base the stopping rule. Default is "residual" for the pooled residual chi-square. Use `type="individual"` to use Wald chi-square of individual factors.
- **sls**: Significance level for staying in a model if `rule="p"`. Default is .05.
- **aics**: For `rule="aic"`, variables are deleted until the chi-square - k.aic times d.f. would rise above aics. Default aics is zero to use the ordinary AIC. Set aics to say 10000 to see all variables deleted in order of descending importance.
- **eps**: Singularity criterion, default is 1E-9.
- **k.aic**: multiplier to compute AIC, default is 2. To use BIC, set `k.aic` equal to \( \log(n) \), where \( n \) is the effective sample size (number of events for survival models).
- **force**: a vector of integers specifying parameters forced to be in the model, not counting intercept(s)
- **x**: result of `fastbw`
- **digits**: number of significant digits to print
- **estimates**: set to `FALSE` to suppress printing table of approximate coefficients, SEs, etc., after variable deletions
- **...**: ignored

Value

A list with an attribute `kept` if `bw=TRUE`, and the following components:

- **result**: matrix of statistics with rows in order of deletion.
- **names.kept**: names of factors kept in final model.
- **factors.kept**: the subscripts of factors kept in the final model
- **factors.deleted**: opposite of `factors.kept`
- **params.kept**: column numbers in design matrix corresponding to parameters kept in the final model.
- **params.deleted**: opposite of `params.kept`
- **coefficients**: vector of approximate coefficients of reduced model.
- **var**: approximate covariance matrix for reduced model.
- **Coefficients**: matrix of coefficients of all models. Rows correspond to the successive models examined and columns correspond to the coefficients in the full model. For variables not in a particular sub-model (row), the coefficients are zero.

Function
Compose an S Function to Compute X beta from a Fit

Description
Function is a class of functions for creating other S functions. Function.rms is the method for creating S functions to compute X beta, based on a model fitted with rms in effect. Like latexrms, Function.rms simplifies restricted cubic spline functions and factors out terms in second-order interactions. Function.rms will not work for models that have third-order interactions involving restricted cubic splines. Function.cph is a particular method for handling fits from cph, for which an intercept (the negative of the centering constant) is added to the model. sascode is a function that takes an S function such as one created by Function and does most of the editing to turn the function definition into a fragment of SAS code for computing X beta from the fitted model, along with assignment statements that initialize predictors to reference values. perlcode similarly creates Perl code to evaluate a fitted regression model.

Usage
## S3 method for class 'rms'
Function(object, intercept=NULL, digits=max(8, .Options$digits), posterior.summary=c('mean', 'median', 'mode'), ...)
## S3 method for class 'cph'
Function(object, intercept=-object$center, ...)

# Use result as fun(predictor1=value1, predictor2=value2, \dots)
sascode(object, file='', append=FALSE)
perlcode(object)
Arguments

- **object**: a fit created with `rms` in effect
- **intercept**: an intercept value to use (not allowed to be specified to `Function.cph`). The intercept is usually retrieved from the regression coefficients automatically.
- **digits**: number of significant digits to use for coefficients and knot locations
- **posterior.summary**: if using a Bayesian model fit such as from `blrm`, specifies whether to use posterior mode/mean/median parameter estimates in generating the function
- **file**: name of a file in which to write the SAS code. Default is to write to standard output.
- **append**: set to `TRUE` to have `sascode` append code to an existing file named `file`.
- **...**: arguments to pass to `Function.rms` from `Function.cph`

Value

Function returns an S-Plus function that can be invoked in any usual context. The function has one argument per predictor variable, and the default values of the predictors are set to adjust-to values (see `datadist`). Multiple predicted $X\beta$ values may be calculated by specifying vectors as arguments to the created function. All non-scalar argument values must have the same length.

`perlcode` returns a character string with embedded newline characters.

sascode(g)
cat(perlcode(g), '\n')
g()
```
gendata

Generate Data Frame with Predictor Combinations

description
If nobs is not specified, allows user to specify predictor settings by e.g. age=50, sex="male", and any omitted predictors are set to reference values (default=median for continuous variables, first level for categorical ones - see datadist). If any predictor has more than one value given, expand.grid is called to generate all possible combinations of values, unless expand=FALSE. If nobs is given, a data frame is first generated which has nobs of adjust-to values duplicated. Then an editor window is opened which allows the user to subset the variable names down to ones which she intends to vary (this streamlines the data.ed step). Then, if any predictors kept are discrete and viewvals=TRUE, a window (using page) is opened defining the possible values of this subset, to facilitate data editing. Then the data.ed function is invoked to allow interactive overriding of predictor settings in the nobs rows. The subset of variables are combined with the other predictors which were not displayed with data.ed, and a final full data frame is returned. gendata is most useful for creating a newdata data frame to pass to predict.

usage

gendata(fit, ..., nobs, viewvals=FALSE, expand=TRUE, factors)

arguments

fit a fit object created with rms in effect

... predictor settings, if nobs is not given.

nobs number of observations to create if doing it interactively using X-windows

viewvals if nobs is given, set viewvals=TRUE to open a window displaying the possible value of categorical predictors
expand set to FALSE to prevent expand.grid from being called, and to instead just convert to a data frame.

factors a list containing predictor settings with their names. This is an alternative to specifying the variables separately in .... Unlike the usage of ...., variables getting default ranges in factors should have NA as their value.

Details

if you have a variable in ... that is named n, no, nob, nob, add nob=FALSE to the invocation to prevent that variable from being misrecognized as nob

Value

a data frame with all predictors, and an attribute names.subset if nob is specified. This attribute contains the vector of variable names for predictors which were passed to de and hence were allowed to vary. If neither nob nor any predictor settings were given, returns a data frame with adjust-to values.

Side Effects

optionally writes to the terminal, opens X-windows, and generates a temporary file using sink.

## End(Not run)

ggplot.Predict

*Plot Effects of Variables Estimated by a Regression Model Fit Using ggplot2*

**Description**

Uses ggplot2 graphics to plot the effect of one or two predictors on the linear predictor or X beta scale, or on some transformation of that scale. The first argument specifies the result of the `Predict` function. The predictor is always plotted in its original coding.

If `rdata` is given, a spike histogram is drawn showing the location/density of data values for the x-axis variable. If there is a `groups` (superposition) variable that generated separate curves, the data density specific to each class of points is shown. This assumes that the second variable was a factor variable. The histograms are drawn by `histSpikeg`.

To plot effects instead of estimates (e.g., treatment differences as a function of interacting factors) see `contrast.rms` and `summary.rms`.

**Usage**

```r
## S3 method for class 'Predict'
ggplot(data, mapping, formula=NULL, groups=NULL,
aestype=c('color', 'linetype'),
conf=c('fill', 'lines'),
conflinetype=1,
varypred=FALSE, sepdiscrte=c('no', 'list', 'vertical', 'horizontal'),
subset, xlim., ylim., xlab, ylab,
colorscale=function(...) scale_color_manual(...,
  values=c("#000000", "#E69F00", "#56B4E9",
    "#009E73", "#F0E442", "#0072B2", "#D55E00", "#CC79A7")),
colfill='black',
rdata=NULL, anova=NULL, pval=FALSE, size.anova=4,
adj.subtitle, size.adj=2.5, perim=NULL, nlevels=3,
flipxdiscrete=TRUE,
legend.position='right', legend.label=NULL,
vnames=c('labels', 'names'), abbrev=FALSE, minlength=6,
layout=NULL, addlayer,
histSpike.opts=list(frac=function(f) 0.01 +
  0.02 * sqrt(f - 1)/sqrt(max(f, 2) - 1), side=1, nint=100),
type=NULL, ggexpr=FALSE, height=NULL, width=NULL, ...), environment)
```
**Arguments**

- **data**: a data frame created by `Predict`
- **mapping**: kept because of ggplot generic setup. If specified it will be assumed to be `formula`.
- **formula**: a ggplot faceting formula of the form `vertical variables ~ horizontal variables`, with variables separated by `*` if there is more than one variable on a side. If omitted, the formula will be built using assumptions on the list of variables that varied in the `Predict` call. When plotting multiple panels (for separate predictors), `formula` may be specified but by default no formula is constructed.
- **groups**: an optional character string containing the name of one of the variables in `data` that is to be used as a grouping (superpositioning) variable. Set `groups=FALSE` to suppress superpositioning. By default, the second varying variable is used for superpositioning groups. You can also specify a length 2 string vector of variable names specifying two dimensions of superpositioning, identified by different aesthetics corresponding to the `aestype` argument. When plotting effects of more than one predictor, groups is a character string that specifies a single variable name in `data` that can be used to form panels. Only applies if using `rbind` to combine several `Predict` results. If there is more than one groups variable, confidence bands are suppressed because `ggplot2:geom_ribbon` does not handle the aesthetics correctly.
- **aestype**: a string vector of aesthetic names corresponding to variables in the `groups` vector. Default is to use, in order, color, and linetype. Other permissible values are size, shape.
- **conf**: specify `conf="line"` to show confidence bands with lines instead of filled ribbons, the default
- **conflinetype**: specify an alternative `linetype` for confidence intervals if `conf="line"
- **varypred**: set to `TRUE` if `data` is the result of passing multiple `Predict` results, that represent different predictors, to `rbind.Predict`. This will cause the `.set` variable created by `rbind` to be copied to the `.predictor` variable.
- **sepdiscrete**: set to something other than "no" to create separate graphics for continuous and discrete predictors. For discrete predictors, horizontal dot charts are produced. This allows use of the `ggplot2:facet_wrap` function to make better use of space. If `sepdiscrete="list"`, a list of two `grid` graphics objects is returned if both types of predictors are present (otherwise one object for the type that existed in the model). Set `sepdiscrete="vertical"` to put the two types of plots into one graphical object with continuous predictors on top and given a fraction of space relative to the number of continuous vs. number of discrete variables. Set `sepdiscrete="horizontal"` to get a horizontal arrangements with continuous variables on the left.
- **subset**: a subsetting expression for restricting the rows of `data` that are used in plotting. For example, predictions may have been requested for males and females but one wants to plot only females.
- **xlim**: This parameter is seldom used, as limits are usually controlled with `Predict`. Usually given as its legal abbreviation `xlim`. One reason to use `xlim` is to plot a factor variable on the x-axis that was created with the `cut2` function with
the `levels.mean` option, with `val.lev=TRUE` specified to `plot.Predict`. In this case you may want the axis to have the range of the original variable values given to `cut2` rather than the range of the means within quantile groups.

**xlab** Label for x-axis. Default is one given to `asis`, `rcs` etc., which may have been the "label" attribute of the variable.

**ylab** Label for y-axis. If `fun` is not given, default is "log Odds" for `lrm`, "log Relative Hazard" for `cph`, name of the response variable for `ols`, `TRUE` or `log(TRUE)` for `psm`, or "X * Beta" otherwise. Specify `ylab=NULL` to omit y-axis labels.

**colorscale** a ggplot2 discrete scale function, e.g. `function(...) scale_color_brewer(..., palette='Set1', type='qual')`. The default is the colorblind-friendly palette including black in http://www.cookbook-r.com/Graphs/Colors_(ggplot2). If you get an error "insufficient values in manual scale", which occurs when there are more than 8 groups, just specify `colorscale=function(...){}` to use default colors.

**colfill** a single character string or number specifying the fill color to use for `geom.ribbon` for shaded confidence bands. Alpha transparency of 0.2 is applied to any color specified.

**rdata** a data frame containing the original raw data on which the regression model were based, or at least containing the x-axis and grouping variable. If `rdata` is present and contains the needed variables, the original data are added to the graph in the form of a spike histogram using `histSpikeg` in the Hmisc package.

**anova** an object returned by `anova.rms`. If `anova` is specified, the overall test of association for predictor plotted is added as text to each panel, located at the spot at which the panel is most empty unless there is significant empty space at the top or bottom of the panel; these areas are given preference.

**pval** specify `pval=TRUE` for `anova` to include not only the test statistic but also the P-value

**size.anova** character size for the test statistic printed on the panel, mm

**adj.subtitle** Set to `FALSE` to suppress subtitling the graph with the list of settings of non-graphed adjustment values. Subtitles appear as captions with ggplot2 using `labs(caption=)`.

**size.adj** Size of adjustment settings in subtitles in mm. Default is 2.5.

**perim** perim specifies a function having two arguments. The first is the vector of values of the first variable that is about to be plotted on the x-axis. The second argument is the single value of the variable representing different curves, for the current curve being plotted. The function’s returned value must be a logical vector whose length is the same as that of the first argument, with values `TRUE` if the corresponding point should be plotted for the current curve, `FALSE` otherwise. See one of the latter examples. `perim` only applies if predictors were specified to `Predict`. 
nlevels

when groups and formula are not specified, if any panel variable has nlevels or fewer values, that variable is converted to a groups (superpositioning) variable. Set nlevels=0 to prevent this behavior. For other situations, a non-numeric x-axis variable with nlevels or fewer unique values will cause a horizontal dot plot to be drawn instead of an x-y plot unless flipxdiscrete=FALSE.

flipxdiscrete

legend.position

"right" (the default for single-panel plots), "left", "bottom", "top", a two-element numeric vector, or "none" to suppress. For multi-panel plots the default is "top", and a legend only appears for the first (top left) panel.

legend.label

if omitted, group variable labels will be used for label the legend. Specify legend.label=FALSE to suppress using a legend name, or a character string or expression to specify the label. Can be a vector is there is more than one grouping variable.

vnames

applies to the case where multiple plots are produced separately by predictor. Set to 'names' to use variable names instead of labels for these small plots.

abbrev

set to true to abbreviate levels of predictors that are categorical to a minimum length of minlength

minlength

see abbrev

layout

for multi-panel plots a 2-vector specifying the number of rows and number of columns. If omitted will be computed from the number of panels to make as square as possible.

addlayer

a ggplot2 expression consisting of one or more layers to add to the current plot

histSpike.opts

a list containing named elements that specifies parameters to histSpikeg when rdata is given. The col parameter is usually derived from other plotting information and not specified by the user.

type

a value ("l","p","b") to override default choices related to showing or connecting points. Especially useful for discrete x coordinate variables.

ggexpr

set to TRUE to have the function return the character string(s) constructed to invoke ggplot without executing the commands

height,width

used if plotly is in effect, to specify the plotly image in pixels. Default is to let plotly size the image.

... ignored

environment ignored; used to satisfy rules because of the generic ggplot

Value

an object of class "ggplot2" ready for printing. For the case where predictors were not specified to Predict, sepdiscrete=TRUE, and there were both continuous and discrete predictors in the model, a list of two graphics objects is returned.

Note

If plotting the effects of all predictors you can reorder the panels using for example p <- Predict(fit); p$.predictor. <- factor(p$.predictor., v) where v is a vector of predictor names specified in the desired order.

gIndex

*Calculate Total and Partial g-indexes for an rms Fit*

**Description**

gIndex computes the total \( g \)-index for a model based on the vector of linear predictors, and the partial \( g \)-index for each predictor in a model. The latter is computed by summing all the terms involving each variable, weighted by their regression coefficients, then computing Gini's mean difference on this sum. For example, a regression model having age and sex and age*sex on the right hand side, with corresponding regression coefficients \( b_1, b_2, b_3 \) will have the \( g \)-index for age computed from Gini's mean difference on the product of age \( \times (b_1 + b_3 w) \) where \( w \) is an indicator set to one for observations with sex not equal to the reference value. When there are nonlinear terms associated with a predictor, these terms will also be combined.

A print method is defined, and there is a plot method for displaying \( g \)-indexes using a dot chart. These functions use Hmisc::GiniMd.

**Usage**

```r
?gIndex(object, partials=TRUE, type=c('ccterm', 'cterms', 'terms'),
        lplabel=if(length(object$scale) && is.character(object$scale))
          object$scale[1] else 'X*Beta',
        fun, funlabel=if(missing(fun)) character(0) else
deparse(substitute(fun)),
```

postfun=if(length(object$scale)==2) exp else NULL,
postlabel=if(length(postfun))
  if((length(object$scale) > 1) &&
    is.character(object$scale)) object$scale[2] else

## S3 method for class 'gIndex'
print(x, digits=4, abbrev=FALSE,
  vnames=c("names","labels"), ...)

## S3 method for class 'gIndex'
plot(x, what=c("pre", "post"),
  xlab=NULL, pch=16, rm.totals=FALSE,
  sort=c("descending", "ascending", "none"), ...)

Arguments

object: result of an rms fitting function

partials: set to FALSE to suppress computation of partial gs

type: defaults to 'ccterm' which causes partial discrimination indexes to be computed after maximally combining all related main effects and interactions. The is usually the only way that makes sense when considering partial linear predictors. Specify type='ccterm' to only combine a main effect with interactions containing it, not also with other main effects connected through interactions. Use type='terms' to separate interactions into their own effects.

lplabel: a replacement for default values such as "X*Beta" or "log odds"/

fun: an optional function to transform the linear predictors before computing the total (only) g. When this is present, a new component gtrans is added to the attributes of the object resulting from gIndex.

funlabel: a character string label for fun, otherwise taken from the function name itself

postfun: a function to transform g such as exp (anti-log), which is the default for certain models such as the logistic and Cox models

postlabel: a label for postfun

...: For gIndex, passed to predict.rms. Ignored for print. Passed to dotchart2 for plot.

x: an object created by gIndex (for print or plot)

digits: causes rounding to the digits decimal place

abbrev: set to TRUE to abbreviate labels if vname="labels"

vnames: set to "labels" to print predictor labels instead of names

what: set to "post" to plot the transformed g-index if there is one (e.g., ratio scale)

xlab: x-axis label; constructed by default
pch  plotting character for point
rm.totals  set to TRUE to remove the total $g$-index when plotting
sort  specifies how to sort predictors by $g$-index; default is in descending order going down the dot chart

Details

For stratification factors in a Cox proportional hazards model, there is no contribution of variation towards computing a partial $g$ except from terms that interact with the stratification variable.

Value

gIndex returns a matrix of class "gIndex" with auxiliary information stored as attributes, such as variable labels. GiniMd returns a scalar.

Glm  
**rms Version of glm**

### Description

This function saves `rms` attributes with the fit object so that `anova.rms`, `Predict`, etc. can be used just as with `ols` and other fits. No validate or calibrate methods exist for `Glm` though.

### Usage

```r
Glm(
  formula,  
  family = gaussian,  
  data = environment(formula),  
  weights,  
  subset,  
  na.action = na.delete,  
  start = NULL,
)```
offset = NULL,
control = glm.control(...),
model = TRUE,
method = "glm.fit",
x = FALSE,
y = TRUE,
contrasts = NULL,
... }

Arguments

formula, family, data, weights, subset, na.action, start, offset, control, model, method, x, y, contrasts see stats::glm(): for print x is the result of Glm
... ignored model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.

Details

For the print method, format of output is controlled by the user previously running options(prType="lang") where lang is "plain" (the default), "latex", or "html".

Value

a fit object like that produced by stats::glm() but with rms attributes and a class of "rms", "Glm", "glm", and "lm". The g element of the fit object is the g-index.

See Also

stats::glm(), Hmisc::GiniMd(), prModFit(), stats::residuals.glm

counts <- c(18,17,15,20,10,20,25,13,12)
outcome <- gl(3,1,9)
treatment <- gl(3,3)
f <- glm(counts ~ outcome + treatment, family=poisson())
f anova(f)
summary(f)
f <- Glm(counts ~ outcome + treatment, family=poisson())
# could have had rcs( ) etc. if there were continuous predictors f
anova(f)
summary(f, outcome=c('1','2','3'), treatment=c('1','2','3'))
Gls  

Fit Linear Model Using Generalized Least Squares

Description

This function fits a linear model using generalized least squares. The errors are allowed to be correlated and/or have unequal variances. Gls is a slightly enhanced version of the Pinheiro and Bates gls function in the nlme package to make it easy to use with the rms package and to implement cluster bootstrapping (primarily for nonparametric estimates of the variance-covariance matrix of the parameter estimates and for nonparametric confidence limits of correlation parameters).

For the print method, format of output is controlled by the user previously running options(prType="lang") where lang is "plain" (the default), "latex", or "html".

Usage

Gls(model, data, correlation, weights, subset, method, na.action=na.omit, control, verbose, B=0, dupCluster=FALSE, pr=FALSE, x=FALSE)

## S3 method for class 'Gls'
print(x, digits=4, coefs=TRUE, title, ...)

Arguments

model  
a two-sided linear formula object describing the model, with the response on the left of a \( \sim \) operator and the terms, separated by + operators, on the right.
data  
an optional data frame containing the variables named in model, correlation, weights, and subset. By default the variables are taken from the environment from which gls is called.
correlation  
an optional corStruct object describing the within-group correlation structure. See the documentation of corClasses for a description of the available corStruct classes. If a grouping variable is to be used, it must be specified in the form argument to the corStruct constructor. Defaults to NULL, corresponding to uncorrelated errors.
weights  
an optional varFunc object or one-sided formula describing the within-group heteroscedasticity structure. If given as a formula, it is used as the argument to varFixed, corresponding to fixed variance weights. See the documentation on varClasses for a description of the available varFunc classes. Defaults to NULL, corresponding to homoscedastic errors.
subset  
an optional expression indicating which subset of the rows of data should be used in the fit. This can be a logical vector, or a numeric vector indicating which observation numbers are to be included, or a character vector of the row names to be included. All observations are included by default.
method  
a character string. If "REML" the model is fit by maximizing the restricted log-likelihood. If "ML" the log-likelihood is maximized. Defaults to "REML".
na.action a function that indicates what should happen when the data contain NAs. The default action (na.omit) results in deletion of observations having any of the variables of interest missing.

control a list of control values for the estimation algorithm to replace the default values returned by the function glsControl. Defaults to an empty list.

verbose an optional logical value. If TRUE information on the evolution of the iterative algorithm is printed. Default is FALSE.

B number of bootstrap resamples to fit and store, default is none

dupCluster set to TRUE to have Gls when bootstrapping to consider multiply-sampled clusters as if they were one large cluster when fitting using the gls algorithm

pr set to TRUE to show progress of bootstrap resampling

x for Gls set to TRUE to store the design matrix in the fit object; otherwise the result of Gls

digits number of significant digits to print

coefs specify coefs=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.

title a character string title to be passed to prModFit

... ignored

Details

The na.delete function will not work with Gls due to some nuance in the model.frame.default function. This probably relates to na.delete storing extra information in the "na.action" attribute of the returned data frame.

Value

an object of classes Gls, rms, and gls representing the linear model fit. Generic functions such as print, plot, ggplot, and summary have methods to show the results of the fit. See glsObject for the components of the fit. The functions resid, coef, and fitted can be used to extract some of its components. Gls returns the following components not returned by gls: Design, assign, formula (see arguments), B (see arguments), bootCoef (matrix of B bootstrapped coefficients), boot.Corr (vector of bootstrapped correlation parameters), Nboot (vector of total sample size used in each bootstrap (may vary if have unbalanced clusters), and var (sample variance-covariance matrix of bootstrapped coefficients). The g-index is also stored in the returned object under the name "g".

**Kaplan-Meier Estimates vs. a Continuous Variable**

**Description**

Function to divide x (e.g. age, or predicted survival at time u created by `survest`) into g quantile groups, get Kaplan-Meier estimates at time u (a scaler), and to return a matrix with columns x=mean x in quantile, n=number of subjects, events=no. events, and KM=K-M survival at time u, std.err = s.e. of -log K-M. Confidence intervals are based on -log S(t). Instead of supplying g, the user
can supply the minimum number of subjects to have in the quantile group (m, default=50). If cuts
is given (e.g. cuts=c(0,.1,.2,...,.9,.1)), it overrides m and g. Calls Therneau's survfitKM in
the survival package to get Kaplan-Meiers estimates and standard errors.

Usage

groupkm(x, Srv, m=50, g, cuts, u,
    pl=FALSE, loglog=FALSE, conf.int=.95, xlab, ylab,
    lty=1, add=FALSE, cex.subtitle=.7, ...)

Arguments

x
variable to stratify

Srv
a Surv object - n x 2 matrix containing survival time and event/censoring 1/0
indicator. Units of measurement come from the "units" attribute of the survival
time variable. "Day" is the default.

m
desired minimum number of observations in a group

g
number of quantile groups

cuts
actual cuts in x, e.g. c(0,1,2) to use [0,1), [1,2].

u
time for which to estimate survival

pl
TRUE to plot results

loglog
set to TRUE to plot log(-log(survival)) instead of survival

conf.int
defaults to .95 for 0.95 confidence bars. Set to FALSE to suppress bars.

xlab
if pl=TRUE, is x-axis label. Default is label(x) or name of calling argument

ylab
if pl=TRUE, is y-axis label. Default is constructed from u and time units at-
tribute.

lty
line time for primary line connecting estimates

add
set to TRUE if adding to an existing plot

cex.subtitle
character size for subtitle. Default is .7. Use FALSE to suppress subtitle.

...
plotting parameters to pass to the plot and errbar functions

Value

matrix with columns named x (mean predictor value in interval), n (sample size in interval), events
(number of events in interval), KM (Kaplan-Meier estimate), std.err (standard error of -log KM)

See Also

survfit, errbar, cut2, Surv, units
Examples

```r
n <- 1000
set.seed(731)
age <- 50 + 12*rnorm(n)
cens <- 15*runif(n)
h <- .02*exp(.04*(age-50))
d.time <- -log(runif(n))/h
label(d.time) <- 'Follow-up Time'
e <- ifelse(d.time <= cens,1,0)
d.time <- pmin(d.time, cens)
units(d.time) <- 'Year'
groupkm(age, Surv(d.time, e), g=10, u=5, pl=TRUE)
#Plot 5-year K-M survival estimates and 0.95 confidence bars by
#decile of age. If omit g=10, will have >= 50 obs./group.
```

---

hazard.ratio.plot  

**Hazard Ratio Plot**

**Description**

The `hazard.ratio.plot` function repeatedly estimates Cox regression coefficients and confidence limits within time intervals. The log hazard ratios are plotted against the mean failure/censoring time within the interval. Unless `times` is specified, the number of time intervals will be \( \max(\text{round}(d/e),2) \), where \( d \) is the total number of events in the sample. Efron’s likelihood is used for estimating Cox regression coefficients (using `coxph.fit`). In the case of tied failure times, some intervals may have a point in common.

**Usage**

```r
hazard.ratio.plot(x, Srv, which, times=, e=30, subset,
conf.int=.95, legendloc=NULL, smooth=TRUE, pr=FALSE, pl=TRUE,
add=FALSE, ylim, cex=.5, xlab="t", ylab, antilog=FALSE, ...)```

**Arguments**

- `x`  
a vector or matrix of predictors
- `Srv`  
a `Surv` object
- `which`  
a vector of column numbers of `x` for which to estimate hazard ratios across time and make plots. The default is to do so for all predictors. Whenever one predictor is displayed, all other predictors in the `x` matrix are adjusted for (with a separate adjustment form for each time interval).
- `times`  
optional vector of time interval endpoints. Example: `times=c(1,2,3)` uses intervals \([0,1), [1,2), [2,3), [3+). If times is omitted, uses intervals containing `e` events
- `e`  
number of events per time interval if `times` not given
- `subset`  
vector used for subsetting the entire analysis, e.g. `subset=sex="female"`
hazard.ratio.plot

collo.gint confidence interval coverage
legendloc location for legend. Omit to use mouse, "none" for none, "ll" for lower left of graph, or actual x and y coordinates (e.g. c(2,3))
smooth also plot the super-smoothed version of the log hazard ratios
pr defaults to FALSE to suppress printing of individual Cox fits
pl defaults to TRUE to plot results
add add this plot to an already existing plot
ylim vector of y-axis limits. Default is computed to include confidence bands.
cex character size for legend information, default is 0.5
xlab label for x-axis, default is "t"
ylab label for y-axis, default is "Log Hazard Ratio" or "Hazard Ratio", depending on antilog.
antilog default is FALSE. Set to TRUE to plot anti-log, i.e., hazard ratio.
... optional graphical parameters

hazard.ratio.plot(age, Surv(d.time,e), e=20, legendloc='ll')
Intervening Event Setup

Description

Creates several new variables which help set up a dataset for modeling with cph or coxph when there is a single binary time-dependent covariable which turns on at a given time, and stays on. This is typical when analyzing the impact of an intervening event. `ie.setup` creates a `Surv` object using the start time, stop time format. It also creates a binary indicator for the intervening event, and a variable called `subs` that is useful when attaching a dataframe. `subs` has observation numbers duplicated for subjects having an intervening event, so those subject's baseline covariables (that are not time-dependent) can be duplicated correctly.

Usage

```r
ie.setup(failure.time, event, ie.time, break.ties=FALSE)
```

Arguments

- `failure.time`: a numeric variable containing the event or censoring times for the terminating event
- `event`: a binary (0/1) variable specifying whether observations had the terminating event (event=1) or were censored (event=0)
- `ie.time`: intervening event times. For subjects having no intervening events, the corresponding values of `ie.time` must be NA.
- `break.ties`: Occasionally intervening events are recorded as happening at exactly the same time as the termination of follow-up for some subjects. The `Surv` and `Surv` functions will not allow this. To randomly break the ties by subtracting a random number from such tied intervening event times, specify `break.ties=TRUE`. The random number is uniform between zero and the minimum difference between any two untied `failure.time` values.

Value

A list with components `S`, `ie.status`, `subs`, `reps`. `S` is a `Surv` object containing start and stop times for intervals of observation, along with event indicators. `ie.status` is one if the intervening event has occurred at the start of the interval, zero otherwise. `subs` is a vector of subscripts that can be used to replicate other variables the same way `S` was replicated. `reps` specifies how many times each original observation was replicated. `S`, `ie.status`, `subs` are all the same length (at least the number of rows for `S` is) and are longer than the original `failure.time` vector. `reps` is the same length as the original `failure.time` vector. The `subs` vector is suitable for passing to `validate.lrm` or `calibrate`, which pass this vector under the name `cluster` on to `predab.resample` so that bootstrapping can be done by sampling with replacement from the original subjects rather than from the individual records created by `ie.setup`. 

Impact of Proportional Odds Assumption

Description

Checks the impact of the proportional odds assumption by comparing predicted cell probabilities from a PO model with those from a multinomial or partial proportional odds logistic model that relax assumptions. For a given model formula, fits the model with both lrm and either nnet::multinom or VGAM::vglm or both, and obtains predicted cell probabilities for the PO and relaxed models on the newdata data frame. A print method formats the output.
Usage

impactPO(
    formula,
    relax = if (missing(nonpo)) "multinomial" else "both",
    nonpo,
    newdata,
    data = environment(formula),
    B = 0,
    ...
)

Arguments

formula a model formula. To work properly with multinom or vglm the terms should
    have completely specified knot locations if a spline function is being used.
relax defaults to "both" if nonpo is given, resulting in fitting two relaxed models. Set
    relax to "multinomial" or "ppo" to fit only one relaxed model. The multinomial
    model does not assume PO for any predictor.
nonpo a formula with no left hand side variable, specifying the variable or variables
    for which PO is not assumed. Specifying nonpo results in a relaxed fit that is a
    partial PO model fitted with VGAM::vglm.
newdata a data frame or data table with one row per covariate setting for which predic-
    tions are to be made
data data frame containing variables to fit; default is the frame in which formula is
    found
B number of bootstrap resamples to do to get confidence intervals for differences
    in predicted probabilities for relaxed methods vs. PO model fits. Default is
    not to run the bootstrap. When running the bootstrap make sure that all model
    variables are explicitly in data= so that selection of random subsets of data will
    call along the correct rows for all predictors.
...
other parameters to pass to lrm and multinom

Value

an impactPO object which is a list with elements estimates, stats, mad, newdata, nboot, and
    boot. estimates is a data frame containing the variables and values in newdata in a tall and
    thin format with additional variable method ("PO", "Multinomial", "PPO"), y (current level of the
    dependent variable), and Probability (predicted cell probability for covariate values and value of
    y in the current row). stats is a data frame containing Deviance the model deviance, d.f. the total
    number of parameters counting intercepts, AIC, p the number of regression coefficients, LR chi^2
    the likelihood ratio chi-square statistic for testing the predictors, LR - p a chance-corrected LR chi-
    square, LR chi^2 test for PO the likelihood ratio chi-square test statistic for testing the PO
    assumption (by comparing -2 log likelihood for a relaxed model to that of a fully PO model), d.f.
    the degrees of freedom for this test, Pr(chi^2) the P-value for this test, MCS R2 the Maddala-
    Cox-Snell R2 using the actual sample size, MCS R2 adj (MCS R2 adjusted for estimating p regression
    coefficients by subtracting p from LR), McFadden R2, McFadden R2 adj (an AIC-like adjustment
    proposed by McFadden without full justification), Mean |difference| from PO the overall mean
absolute difference between predicted probabilities over all categories of Y and over all covariate settings. mad contains newdata and separately by rows in newdata the mean absolute difference (over Y categories) between estimated probabilities by the indicated relaxed model and those from the PO model. nboot is the number of successful bootstrap repetitions, and boot is a 4-way array with dimensions represented by the nboot resamples, the number of rows in newdata, the number of outcome levels, and elements for PPO and multinomial. For the modifications of the Maddala-Cox-Snell indexes see Hmisc::R2Measures.

latex.cph

*LaTeX Representation of a Fitted Cox Model*

### Description

Creates a file containing a LaTeX representation of the fitted model.

### Usage

```r
## S3 method for class 'cph'
latex(object, title,
  file='',
  append=FALSE, surv=TRUE, maxt=FALSE, which=NULL, varnames, columns=65,
  inline=FALSE, before=if(inline)'' else ''&'', after=''', dec=3,
  pretrans=TRUE, caption, digits=.Options$ digits, size='',
  ...) # for cph fit

## S3 method for class 'lrm'
latex(object, title, file, append, which, varnames,
  columns, inline, before, after, pretrans, caption,
  digits=.Options$ digits, size='', ...) # for lrm fit

## S3 method for class 'ols'
latex(object, title, file, append, which, varnames,
  columns, inline, before, after, pretrans, caption,
  digits=.Options$ digits, size='', ...) # for ols fit

## S3 method for class 'orm'
latex(object, title, file, append, which, varnames,
  columns, inline, before, after, pretrans, caption,
  digits=.Options$ digits, size='', intercepts=nrp < 10, ...) # for orm fit

## S3 method for class 'pphsm'
latex(object, title, file, append, which=NULL, varnames,
  columns, inline, before, after, pretrans, caption,
  digits=.Options$ digits, size='', ...) # pphsm fit

## S3 method for class 'psm'
latex(object, title, file, append, which=NULL, varnames,
  columns, inline, before, after, pretrans, caption,
  digits=.Options$ digits, size='', ...) # psm fit
```

Arguments

object  a fit object created by a `rms` fitting function.
title   ignored
file, append  see `latex.default`. Defaults to the console. When using html/markdown, `file` is ignored.
surv    if `surv=TRUE` was specified to `cph`, the underlying survival probabilities from `object$surv.summary` will be placed in a table unless `surv=FALSE`.
maxt    if the maximum follow-up time in the data (`object$maxtime`) exceeds the last entry in `object$surv.summary`, underlying survival estimates at `object$maxtime` will be added to the table if `maxt=TRUE`.
which, varnames, columns, inline, before, dec, pretrans see `latex.default`
after   if not an empty string, added to end of markup if `inline=TRUE`
caption a character string specifying a title for the equation to be centered and typeset in bold face. Default is no title.
digits  see `latexrms`
size    a LaTeX size to use, without the slash. Default is the prevailing size
intercepts for `orm` fits. Default is to print intercepts if they are fewer than 10 in number. Set to `TRUE` or `FALSE` to force.
...     ignored

Value

the name of the created file, with class `c("latex","file")`. This object works with latex viewing and printing commands in Hmisc.

Examples

```r
## Not run:
units(ftime) <- "Day"
f <- cph(Surv(ftime, death) ~ rcs(age)+sex, surv=TRUE, time.inc=60)
w <- latex(f, file="f.tex")  #Interprets fitted model and makes table of S_0(t)
  #for t=0,60,120,180,...
w  #displays image, if viewer installed and file given above
latex(f)  # send LaTeX code to the console for knitr
options(prType='html')
```
latex rms

LaTeX Representation of a Fitted Model

Description

Creates a file containing a LaTeX representation of the fitted model. For model-specific typesetting there is latex.lrm, latex.cph, latex.psm and latex.ols. latex.cph has some arguments that are specific to cph models. latex.rms is the core function which is called internally by latex.rms (which is called by latex.cph, latex.ols, etc.). html and R Markdown-compatible markup (using MathJax) are written if options(prType='html').

Usage

latex.rms(object, file='', append=FALSE, which=1:p, varnames, columns=65, prefix=NULL, inline=FALSE, before=if(inline)"" else " & ", after='', intercept, pretrans=TRUE, digits=.Options$digits, size="")

Arguments

object a fit object created by a fitting function in the rms series

file name of .tex file to create, default is to write to console. file is ignored when options(prType='html').

append whether or not to append to an existing file

which a vector of subscripts (corresponding to object$Design$name) specifying a sub-model to print. Default is to describe the whole model. can also be a vector of character strings specifying the factor names to print. Enough of each string is needed to ensure a unique match. Names for interaction effects are of the form "age * sex". For any interaction effect for which you do not request main effects, the main effects will be added to which. When which is given, the model structural statement is not included. In this case, intercepts are not included either.

varnames variable names to substitute for non-interactions. Order must correspond to object$Design$name and interactions must be omitted. Default is object$Design$name[object$Design$assume.code!=9]. varnames can contain any LaTeX commands such as subscripts and "\frac" (all "\\" must be quadrupled.) Any "/" must be preceded by "\\" (2, not 4 backslashes). Elements of varnames for interactions are ignored; they can be set to any value.

columns maximum number of columns of printing characters to allow before outputting a LaTeX newline command
prefix: if given, a LaTeX {\texttt{\textbackslash lefteqn}} command of the form \texttt{\textbackslash lefteqn\{prefix =\}} {\textbackslash \textbackslash} will be inserted to print a left-hand-side of the equation.

inline: Set to \texttt{TRUE} to create text for insertion in an in-line equation. This text contains only the expansion of \texttt{X beta}, and is not surrounded by "$".

before: a character string to place before each line of output. Use the default for a LaTeX \texttt{eqnarray} environment. For \texttt{inline=TRUE}, the before string, if not an empty string, will be placed once before the entire markup.

after: a character string to place after the output if \texttt{inline=TRUE}

intercept: a special intercept value to include that is not part of the standard model parameters (e.g., centering constant in Cox model). Only allowed in the \texttt{latexrms} rendition.

pretrans: if any spline or polynomial-expanded variables are themselves transformed, a table of pre-transformations will be formed unless \texttt{pretrans=FALSE}.

digits: number of digits of precision to use in formatting coefficients and other numbers

size: a LaTeX font size to use for the output, without the slash. Default is current size.

Value

a file name of class "latex", or if \texttt{options(prType='html')}, nothing (output direct to console)

Examples

```r
## Not run:
f <- lrm(death ~ rcs(age)+sex)
w <- latex(f, file='f.tex')
w  # displays, using e.g. xdvi
latex(f)  # send LaTeX code to console, as for knitr
options(prType='html')
latex(f)  # emit html and latex for knitr html and html notebooks
## End(Not run)
```
**Description**

Fit binary and proportional odds ordinal logistic regression models using maximum likelihood estimation or penalized maximum likelihood estimation. See `cr.setup` for how to fit forward continuation ratio models with `lrm`.

For the `print` method, format of output is controlled by the user previously running `options(prType="lang")` where `lang` is "plain" (the default), "latex", or "html".

**Usage**

```r
lrm(formula, data=environment(formula),
    subset, na.action=na.delete, method="lrm.fit",
    model=FALSE, x=FALSE, y=FALSE, linear.predictors=TRUE, se.fit=FALSE,
    penalty=0, penalty.matrix, tol=1e-7,
    strata.penalty=0, var.penalty=c('simple','sandwich'),
    weights, normwt, scale=FALSE, ...)
```

```r
## S3 method for class 'lrm'
print(x, digits=4, r2=c(0,2,4), strata.coefs=FALSE,
    coefs=TRUE, pg=FALSE, title="Logistic Regression Model", ...)
```

**Arguments**

- `formula` a formula object. An `offset` term can be included. The offset causes fitting of a model such as \( \logit(Y = 1) = X\beta + W \), where \( W \) is the offset variable having no estimated coefficient. The response variable can be any data type; `lrm` converts it in alphabetic or numeric order to an S factor variable and recodes it 0,1,2,... internally.
- `data` data frame to use. Default is the current frame.
- `subset` logical expression or vector of subscripts defining a subset of observations to analyze.
- `na.action` function to handle NAs in the data. Default is `na.delete`, which deletes any observation having response or predictor missing, while preserving the attributes of the predictors and maintaining frequencies of deletions due to each variable in the model. This is usually specified using `options(na.action="na.delete")`.
- `method` name of fitting function. Only allowable choice at present is `lrm.fit`.
- `model` causes the model frame to be returned in the fit object.
- `x` causes the expanded design matrix (with missings excluded) to be returned under the name `x`. For `print`, an object created by `lrm`.
- `y` causes the response variable (with missings excluded) to be returned under the name `y`. 
linear.predictors
causes the predicted X beta (with missings excluded) to be returned under the name linear.predictors. When the response variable has more than two levels, the first intercept is used.

se.fit
causes the standard errors of the fitted values to be returned under the name se.fit.

tolerance
The penalty factor subtracted from the log likelihood is \(0.5\beta'P\beta\), where \(\beta\) is the vector of regression coefficients other than intercept(s), and \(P\) is penalty factors × penalty.matrix and penalty.matrix is defined below. The default is penalty=0 implying that ordinary unpenalized maximum likelihood estimation is used. If penalty is a scalar, it is assumed to be a penalty factor that applies to all non-intercept parameters in the model. Alternatively, specify a list to penalize different types of model terms by differing amounts. The elements in this list are named simple, nonlinear, interaction and nonlinear.interaction. If you omit elements on the right of this series, values are inherited from elements on the left. Examples: penalty=list(simple=5, nonlinear=10) uses a penalty factor of 10 for nonlinear or interaction terms. penalty=list(simple=0, nonlinear=2, nonlinear.interaction=4) does not penalize linear main effects, uses a penalty factor of 2 for nonlinear or interaction effects (that are not both), and 4 for nonlinear interaction effects.

penalty.matrix
specifies the symmetric penalty matrix for non-intercept terms. The default matrix for continuous predictors has the variance of the columns of the design matrix in its diagonal elements so that the penalty to the log likelihood is unitless. For main effects for categorical predictors with \(c\) categories, the rows and columns of the matrix contain a \((c-1) \times (c-1)\) sub-matrix that is used to compute the sum of squares about the mean of the \(c\) parameter values (setting the parameter to zero for the reference cell) as the penalty component for that predictor. This makes the penalty independent of the choice of the reference cell. If you specify penalty.matrix, you may set the rows and columns for certain parameters to zero so as to not penalize those parameters. Depending on penalty, some elements of penalty.matrix may be overridden automatically by setting them to zero. The penalty matrix that is used in the actual fit is 
\[penalty \times \text{diag}(pf) \times \text{penalty.matrix} \times \text{diag}(pf)\], where \(pf\) is the vector of square roots of penalty factors computed from penalty by Penalty.setup in rmsMisc. If you specify penalty.matrix you must specify a nonzero value of penalty or no penalization will be done.

tol
singularity criterion (see lrm.fit)

strata.penalty
scalar penalty factor for the stratification factor, for the experimental strat variable

var.penalty
the type of variance-covariance matrix to be stored in the var component of the fit when penalization is used. The default is the inverse of the penalized information matrix. Specify var.penalty="sandwich" to use the sandwich estimator (see below under var), which limited simulation studies have shown yields variances estimates that are too low.

weights
a vector (same length as \(y\)) of possibly fractional case weights

normwt
set to TRUE to scale weights so they sum to the length of \(y\); useful for sample surveys as opposed to the default of frequency weighting
scale

set to TRUE to subtract means and divide by standard deviations of columns of the design matrix before fitting, and to back-solve for the un-normalized covariance matrix and regression coefficients. This can sometimes make the model converge for very large sample sizes where for example spline or polynomial component variables create scaling problems leading to loss of precision when accumulating sums of squares and crossproducts.

... arguments that are passed to lrm.fit, or from print, to prModFit
digits

number of significant digits to use

r2

vector of integers specifying which R^2 measures to print, with 0 for Nagelkerke R^2 and 1:4 corresponding to the 4 measures computed by R2Measures. Default is to print Nagelkerke (labeled R2) and second and fourth R2Measures which are the measures adjusted for the number of predictors, first for the raw sample size then for the effective sample size, which here is from the formula for the approximate variance of a log odds ratio in a proportional odds model.

strata.coefs

set to TRUE to print the (experimental) strata coefficients
coeffs

specify coef=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coef=n to print only the first n regression coefficients in the model.

pg

set to TRUE to print g-indexes
title

a character string title to be passed to prModFit

Value

The returned fit object of lrm contains the following components in addition to the ones mentioned under the optional arguments.

call
calling expression

digits
table of frequencies for Y in order of increasing Y

stats

vector with the following elements: number of observations used in the fit, maximum absolute value of first derivative of log likelihood, model likelihood ratio $\chi^2$, d.f., $P$-value, c index (area under ROC curve), Somers' $D_{xy}$, Goodman-Kruskal $\gamma$, Kendall's $\tau_a$ rank correlations between predicted probabilities and observed response, the Nagelkerke $R^2$ index, the Brier score computed with respect to $Y >$ its lowest level, the $g$-index, $gr$ (the $g$-index on the odds ratio scale), and $gp$ (the $g$-index on the probability scale using the same cutoff used for the Brier score). Probabilities are rounded to the nearest 0.0002 in the computations or rank correlation indexes. In the case of penalized estimation, the "Model L.R." is computed without the penalty factor, and "d.f." is the effective d.f. from Gray's (1992) Equation 2.9. The $P$-value uses this corrected model L.R. $\chi^2$ and corrected d.f. The score chi-square statistic uses first derivatives which contain penalty components.

fail

set to TRUE if convergence failed (and maxiter>1)

coefficients

estimated parameters

var

estimated variance-covariance matrix (inverse of information matrix). If penalty>0, var is either the inverse of the penalized information matrix (the default, if
var.penalty="simple") or the sandwich-type variance-covariance matrix estimate (Gray Eq. 2.6) if var.penalty="sandwich". For the latter case the simple information-matrix-based variance matrix is returned under the name var.from.info.matrix.

effective.df.diagonal

is returned if penalty>0. It is the vector whose sum is the effective d.f. of the model (counting intercept terms).

u

vector of first derivatives of log-likelihood

deviance

-2 log likelihoods (counting penalty components) When an offset variable is present, three deviances are computed: for intercept(s) only, for intercepts+offset, and for intercepts+offset+predictors. When there is no offset variable, the vector contains deviances for the intercept(s)-only model and the model with intercept(s) and predictors.

est

vector of column numbers of X fitted (intercepts are not counted)

non.slopes

number of intercepts in model

penalty

see above

penalty.matrix

the penalty matrix actually used in the estimation

new.data <- data.frame(x1,x2,x3,y)[301:500,]
for(penlty in seq(0,.15,by=.005)) {
  if(penlty==0) {
    f <- lrm(y ~ rcs(x1,4)+rcs(x2,6)*x3, subset=1:300, x=TRUE, y=TRUE)
    # True model is linear in x1 and has no interaction
    X <- f$x # saves time for future runs - don't have to use rcs etc.
    Y <- f$y # this also deletes rows with NAs (if there were any)
    penalty.matrix <- diag(diag(var(X)))
    Xnew <- predict(f, new.data, type="x")
    # expand design matrix for new data
    Ynew <- new.data$y
  } else f <- lrm.fit(X,Y, penalty.matrix=penlty*penalty.matrix)
  cat("Penalty :",penlty,"\n")
pred.logit <- f$coef[1] + (Xnew %*% f$coef[-1])
pred <- plogis(pred.logit)
C.index <- somers2(pred, Ynew)\"C\"
Brier <- mean((pred-Ynew)^2)
Deviance <- -2*sum(Ynew*log(pred) + (1-Ynew)*log(1-pred) )
cat("ROC area:\",format(C.index)," Brier score:\",format(Brier),
" -2 Log L:\",format(Deviance),"\n")
}
# penalty=0.045 gave lowest -2 Log L, Brier, ROC in test sample for S+
# Use bootstrap validation to estimate predictive accuracy of
# logistic models with various penalties
To see how noisy cross-validation estimates can be, change the 
`validate(f, \dots)` to `validate(f, method="cross", B=10)` for example. 
You will see tremendous variation in accuracy with minute changes in 
the penalty. This comes from the error inherent in using 10-fold 
cross validation but also because we are not fixing the splits. 
20-fold cross validation was even worse for some 
indexes because of the small test sample size. Stability would be 
obtained by using the same sample splits for all penalty values 
(see above), but then we wouldn’t be sure that the choice of the 
best penalty is not specific to how the sample was split. This 
problem is addressed in the last example.

```r
penalties <- seq(0,.7,length=3) # really use by=.02
index <- matrix(NA, nrow=length(penalties), ncol=11,
    dimnames=list(format(penalties),
        c("Dxy","R2","Intercept","Slope","Emax","D","U","Q","B","g","gp")))
i <- 0
for(penlty in penalties)
{
    cat(penlty, "")
    i <- i+1
    if(penlty==0)
    {
        f <- lrm(y ~ rcs(x1,4)+rcs(x2,6)*x3, x=TRUE, y=TRUE) # fit whole sample
        X <- f$x
        Y <- f$y
        penalty.matrix <- diag(diag(var(X))) # save time - only do once
    }
    else
    f <- lrm(Y ~ X, penalty=penlty,
        penalty.matrix=penalty.matrix, x=TRUE,y=TRUE)
    val <- validate(f, method="boot", B=20) # use larger B in practice
    index[i,] <- val[,"index.corrected"]
}
par(mfrow=c(3,3))
for(i in 1:9)
{
    plot(penalties, index[,i],
        xlab="Penalty", ylab=dimnames(index)[[2]][i])
    lines(lowess(penalties, index[,i]))
}
options(datadist=NULL)
```

Example of weighted analysis
```r
x <- 1:5
y <- c(0,1,0,1,0)
reps <- c(1,2,3,2,1)
lrm(y ~ x, weights=reps)
x <- rep(x, reps)
y <- rep(y, reps)
lrm(y ~ x) # same as above
```
#Study performance of a modified AIC which uses the effective d.f.
#Also try as effective d.f. equation (4) of the previous reference.
#Also study performance of Shao’s cross-validation technique (which was
designed to pick the “right” set of variables, and uses a much smaller
training sample than most methods). Compare cross-validated deviance
vs. penalty to the gold standard accuracy on a 7500 observation dataset.
#Note that if you only want to get AIC or Schwarz Bayesian information
criterion, all you need is to invoke the pentrace function.
#NOTE: the effective.df( ) function is used in practice
#

## End(Not run)
# The results showed that to obtain a clear picture of the penalty-
# accuracy relationship one needs 30 or 40 reps in the cross-validation.
# For 4 of 5 samples, though, the super smoother was able to detect
# an accurate penalty giving the best (lowest) deviance using 10-fold
# cross-validation. Cross-validation would have worked better had
# the same splits been used for all penalties.
# The AIC methods worked just as well and are much quicker to compute.
# The first AIC based on the effective d.f. in Gray's Eq. 2.9
# (Verweij and Van Houwelingen (1994) Eq. 5 (note typo)) worked best.

---

**lrn.fit**

**Logistic Model Fitter**
**Description**

Fits a binary or ordinal logistic model for a given design matrix and response vector with no missing values in either. Ordinary or penalized maximum likelihood estimation is used.

**Usage**

```r
lrm.fit(x, y, offset=0, initial, est, maxit=12, eps=.025,
       tol=1e-7, trace=FALSE, penalty.matrix=NULL, weights=NULL,
       normwt=FALSE, scale=FALSE)
```

**Arguments**

- `x`: design matrix with no column for an intercept
- `y`: response vector, numeric, categorical, or character
- `offset`: optional numeric vector containing an offset on the logit scale
- `initial`: vector of initial parameter estimates, beginning with the intercept
- `est`: indexes of `x` to fit in the model (default is all columns of `x`). Specifying `est=c(1,2,5)` causes columns 1, 2, and 5 to have parameters estimated. The score vector `u` and covariance matrix `var` can be used to obtain score statistics for other columns
- `maxit`: maximum no. iterations (default = 12). Specifying `maxit=1` causes logist to compute statistics at initial estimates.
- `eps`: difference in $-2\log$ likelihood for declaring convergence. Default is .025. If the $-2\log$ likelihood gets worse by `eps/10` while the maximum absolute first derivative of $-2\log$ likelihood is below 1e-9, convergence is still declared. This handles the case where the initial estimates are MLEs, to prevent endless step-halving.
- `tol`: Singularity criterion. Default is 1e-7
- `trace`: set to `TRUE` to print $-2\log$ likelihood, step-halving fraction, change in $-2\log$ likelihood, maximum absolute value of first derivative, and vector of first derivatives at each iteration.
- `penalty.matrix`: a self-contained ready-to-use penalty matrix - see `lrm`
- `weights`: a vector (same length as `y`) of possibly fractional case weights
- `normwt`: set to `TRUE` to scale weights so they sum to the length of `y`; useful for sample surveys as opposed to the default of frequency weighting
- `scale`: set to `TRUE` to subtract column means and divide by column standard deviations of `x` before fitting, and to back-solve for the un-normalized covariance matrix and regression coefficients. This can sometimes make the model converge for very large sample sizes where for example spline or polynomial component variables create scaling problems leading to loss of precision when accumulating sums of squares and crossproducts.

**Value**

A list with the following components:
call calling expression
freq table of frequencies for \( y \) in order of increasing \( y \)
stats vector with the following elements: number of observations used in the fit, maximum absolute value of first derivative of log likelihood, model likelihood ratio chi-square, d.f., P-value, \( c \) index (area under ROC curve), Somers’ \( D_{xy} \), Goodman-Kruskal \( \gamma \), and Kendall’s \( \tau_a \) rank correlations between predicted probabilities and observed response, the Nagelkerke \( R^2 \) index, 4 indexes computed by \textit{R2Measures}, the Brier probability score with respect to computing the probability that \( y > \) the mid level less one, the \( g \)-index, \( gr \) (the \( g \)-index on the odds ratio scale), and \( gp \) (the \( g \)-index on the probability scale using the same cutoff used for the Brier score). Probabilities are rounded to the nearest 0.002 in the computations or rank correlation indexes. When \texttt{penalty.matrix} is present, the \( \chi^2 \), d.f., and P-value are not corrected for the effective d.f.
fail set to \texttt{TRUE} if convergence failed (and maxit>1)
coefficients estimated parameters
var estimated variance-covariance matrix (inverse of information matrix). Note that in the case of penalized estimation, \texttt{var} is not the improved sandwich-type estimator (which \texttt{lrm} does compute).
u vector of first derivatives of log-likelihood
deviance -2 log likelihoods. When an offset variable is present, three deviances are computed: for intercept(s) only, for intercepts+offset, and for intercepts+offset+predictors. When there is no offset variable, the vector contains deviances for the intercept(s)-only model and the model with intercept(s) and predictors.
est vector of column numbers of \( X \) fitted (intercepts are not counted)
non.slopes number of intercepts in model
penalty.matrix see above

\textbf{See Also}

\texttt{lrm, glm, matinv, solvet, cr.setup, gIndex}

\textbf{Examples}

```
# Fit an additive logistic model containing numeric predictors age,
# blood.pressure, and sex, assumed to be already properly coded and
# transformed
#
# fit <- lrm.fit(cbind(age,blood.pressure,sex), death)
```
Description

Bare Bones Logistic Regression Fit

Usage

```r
lrm.fit.bare(x, y, maxit = 12, eps = 0.025, tol = 1e-07)
```

Arguments

- `x`: a vector of matrix of covariate values
- `y`: a numeric or factor vector representing the dependent variable
- `maxit`: maximum number of iterations
- `eps`: stopping criterion (change in -2 log likelihood)
- `tol`: matrix inversion tolerance for singularities

Details

This is a stripped down version of the `lrm.fit()` function that computes only the regression coefficients, variance-covariance-matrix, and log likelihood (for null and fitted model) and does not compute any model fit indexes etc. This is for speed in simulations or with bootstrapping. Missing data are not allowed. The function handles binary and ordinal logistic regression (proportional odds model).

Value

A list with elements `coefficients`, `var`, `fail`, `freq`, `deviance`

Author(s)

Frank Harrell
Description

This function inverts or partially inverts a matrix using pivoting (the sweep operator). It is useful for sequential model-building.

Usage

```r
matinv(a, which, negate=TRUE, eps=1e-12)
```

Arguments

- `a`: square matrix to invert or partially invert. May have been inverted or partially inverted previously by `matinv`, in which case its "swept" attribute is updated. Will un-invert if already inverted.
- `which`: vector of column/row numbers in `a` to invert. Default is all, for total inverse.
- `negate`: So that the algorithm can keep track of which pivots have been swept as well as roundoff errors, it actually returns the negative of the inverse or partial inverse. By default, these elements are negated to give the usual expected result. Set `negate=FALSE` if you will be passing the result right back into `matinv`, otherwise, negate the submatrix before sending back to `matinv`.
- `eps`: singularity criterion

Value

A square matrix, with attributes "rank" and "swept".

References

`lrm`, `solve`
Examples

```r
a <- diag(1:3)
a.inv1 <- matinv(a, 1, negate=FALSE)  # Invert with respect to a[1,1]
a.inv1
a.inv <- -matinv(a.inv1, 2:3, negate=FALSE)  # Finish the job
a.inv
solve(a)
```

---

**nomogram**

**Draw a Nomogram Representing a Regression Fit**

### Description

Draws a partial nomogram that can be used to manually obtain predicted values from a regression model that was fitted with `rms`. The nomogram does not have lines representing sums, but it has a reference line for reading scoring points (default range 0–100). Once the reader manually totals the points, the predicted values can be read at the bottom. Non-monotonic transformations of continuous variables are handled (scales wrap around), as are transformations which have flat sections (tick marks are labeled with ranges). If interactions are in the model, one variable is picked as the "axis variable", and separate axes are constructed for each level of the interacting factors (preference is given automatically to using any discrete factors to construct separate axes) and levels of factors which are indirectly related to interacting factors (see DETAILS). Thus the nomogram is designed so that only one axis is actually read for each variable, since the variable combinations are disjoint. For categorical interacting factors, the default is to construct axes for all levels. The user may specify coordinates of each predictor to label on its axis, or use default values. If a factor interacts with other factors, settings for one or more of the interacting factors may be specified separately (this is mandatory for continuous variables). Optional confidence intervals will be drawn for individual scores as well as for the linear predictor. If more than one confidence level is chosen, multiple levels may be displayed using different colors or gray scales. Functions of the linear predictors may be added to the nomogram.

The `datadist` object that was in effect when the model was fit is used to specify the limits of the axis for continuous predictors when the user does not specify tick mark locations in the `nomogram` call.

`print.nomogram` prints axis information stored in an object returned by `nomogram`. This is useful in producing tables of point assignments by levels of predictors. It also prints how many linear predictor units there are per point and the number of points per unit change in the linear predictor.

`legend.nomabbrev` draws legends describing abbreviations used for labeling tick marks for levels of categorical predictors.

### Usage

```r
nomogram(fit, ..., adj.to, lp=TRUE, lp.at=NULL,
   fun=NULL, fun.at=NULL, fun.lp.at=NULL, funlabel="Predicted Value",
   interact=NULL, kint=NULL, conf.int=FALSE,
   conf.lp=c("representative", "all", "none"),
   est.all=TRUE, posterior.summary=c('mean', 'median', 'mode'),
)```

## S3 method for class 'nomogram'
print(x, dec=0, ...) 

## S3 method for class 'nomogram'
plot(x, lplabel="Linear Predictor", fun.side, 
col.conf=c(1, .3), 
conf.space=c(.08,.2), label.every=1, force.label=FALSE, 
xfrac=.35, cex.axis=.85, cex.var=1, col.grid=NULL, 
varname.label=TRUE, varname.label.sep="=", ia.space=.7, 
tck=NA, tcl=-0.25, lmgp=.4, naxes, 
points.label='Points', total.points.label='Total Points', 
total.sep.page=FALSE, total.fun, cap.labels=FALSE, ...) 

legend.nomabbrev(object, which, x, y, ncol=3, ...) 

Arguments

fit a regression model fit that was created with rms, and (usually) with options(datadist = "object.name") in effect.

... settings of variables to use in constructing axes. If datadist was in effect, the default is to use pretty(total range, nint) for continuous variables, and the class levels for discrete ones. For legend.nomabbrev, ... specifies optional parameters to pass to legend. Common ones are bty = "n" to suppress drawing the box. You may want to specify a non-proportionally spaced font (e.g., courier) number if abbreviations are more than one letter long. This will make the abbreviation definitions line up (e.g., specify font = 2, the default for courier). Ignored for print and plot.

adj.to If you didn’t define datadist for all predictors, you will have to define adjustment settings for the undefined ones, e.g. adj.to=list(age = 50, sex = "female").

lp Set to FALSE to suppress creation of an axis for scoring $X\beta$.

lp.at If lp=TRUE, lp.at may specify a vector of settings of $X\beta$. Default is to use pretty(range of linear predictors, nint).

fun an optional function to transform the linear predictors, and to plot on another axis. If more than one transformation is plotted, put them in a list, e.g. list(function(x) x/2, function(x) 2*x). Any function values equal to NA will be ignored.

fun.at function values to label on axis. Default fun evaluated at lp.at. If more than one fun was specified, using a vector for fun.at will cause all functions to be evaluated at the same argument values. To use different values, specify a list of vectors for fun.at, with elements corresponding to the different functions (lists of vectors also applies to fun.lp.at and fun.side).
fun.lp.at: If you want to evaluate one of the functions at a different set of linear predictor values than may have been used in constructing the linear predictor axis, specify a vector or list of vectors of linear predictor values at which to evaluate the function. This is especially useful for discrete functions. The presence of this attribute also does away with the need for `nomogram` to compute numerical approximations of the inverse of the function. It also allows the user-supplied function to return factor objects, which is useful when e.g. a single tick mark position actually represents a range. If the `fun.lp.at` parameter is present, the `fun.at` vector for that function is ignored.

fun.label: label for `fun` axis. If more than one function was given but `fun.label` is of length one, it will be duplicated as needed. If `fun` is a list of functions for which you specified names (see the final example below), these names will be used as labels.

interact: When a continuous variable interacts with a discrete one, axes are constructed so that the continuous variable moves within the axis, and separate axes represent levels of interacting factors. For interactions between two continuous variables, all but the axis variable must have discrete levels defined in `interact`. For discrete interacting factors, you may specify levels to use in constructing the multiple axes. For continuous interacting factors, you must do this. Examples: `interact = list(age = seq(10, 70, by=10), treat = c("A", "B", "D"));`.

kint: for models such as the ordinal models with multiple intercepts, specifies which one to use in evaluating the linear predictor. Default is to use `fit$interceptRef` if it exists, or 1.

cnf.int: confidence levels to display for each scoring. Default is FALSE to display no confidence limits. Setting `cnf.int` to TRUE is the same as setting it to c(0.7, 0.9), with the line segment between the 0.7 and 0.9 levels shaded using gray scale.

cnf.lp: default is "representative" to group all linear predictors evaluated into deciles, and to show, for the linear predictor confidence intervals, only the mean linear predictor within the deciles along with the median standard error within the deciles. Set `cnf.lp = "none"` to suppress confidence limits for the linear predictors, and to "all" to show all confidence limits.

est.all: To plot axes for only the subset of variables named in . . . set `est.all = FALSE`. Note: This option only works when zero has a special meaning for the variables that are omitted from the graph.

posterior.summary: when operating on a Bayesian model such as a result of `blrm` specifies whether to use posterior mean (default) vs. posterior mode/median of parameter values in constructing the nomogram.

abbrev: Set to TRUE to use the `abbreviate` function to abbreviate levels of categorical factors, both for labeling tick marks and for axis titles. If you only want to abbreviate certain predictor variables, set `abbrev` to a vector of character strings containing their names.

minlength: applies if `abbrev = TRUE`. Is the minimum abbreviation length passed to the `abbreviate` function. If you set `minlength = 1`, the letters of the alphabet are used to label tick marks for categorical predictors, and all letters are drawn
nomogram

no matter how close together they are. For labeling axes (interaction settings), minlength = 1 causes minlength = 4 to be used.

maxscale

default maximum point score is 100

nint

number of intervals to label for axes representing continuous variables. See pretty.

vnames

By default, variable labels are used to label axes. Set vnames = "names" to instead use variable names.

omit

text of character strings containing names of variables for which to suppress drawing axes. Default is to show all variables.

verbose

set to TRUE to get printed output detailing how tick marks are chosen and labeled for function axes. This is useful in seeing how certain linear predictor values cannot be solved for using inverse linear interpolation on the (requested linear predictor values, function values at these lp values). When this happens you will see NAs in the verbose output, and the corresponding tick marks will not appear in the nomogram.

x

an object created by nomogram, or the x coordinate for a legend

dec

number of digits to the right of the decimal point, for rounding point scores in print.nomogram. Default is to round to the nearest whole number of points.

lplabel

label for linear predictor axis. Default is "Linear Predictor".

fun.side

a vector or list of vectors of side parameters for the axis function for labeling function values. Values may be 1 to position a tick mark label below the axis (the default), or 3 for above the axis. If for example an axis has 5 tick mark labels and the second and third will run into each other, specify fun.side=c(1,1,3,1,1) (assuming only one function is specified as fun).

col.conf

colors corresponding to conf.int.

col.space

a 2-element vector with the vertical range within which to draw confidence bars, in units of 1 = spacing between main bars. Four heights are used within this range (8 for the linear predictor if more than 16 unique values were evaluated), cycling them among separate confidence intervals to reduce overlapping.

label.every

Specify label.every = 1 to label on every 1th tick mark.

force.label

set to TRUE to force every tick mark intended to be labeled to have a label plotted (whether the labels run into each other or not)

xfrac

fraction of horizontal plot to set aside for axis titles

cex.axis

character size for tick mark labels

cex.var

character size for axis titles (variable names)

col.grid

If left unspecified, no vertical reference lines are drawn. Specify a vector of length one (to use the same color for both minor and major reference lines) or two (corresponding to the color for the major and minor divisions, respectively) containing colors, to cause vertical reference lines to the top points scale to be drawn. For R, a good choice is col.grid = gray(c(0.8, 0.95)).

varname.label

In constructing axis titles for interactions, the default is to add (interacting.varname = level) on the right. Specify varname.label = FALSE to instead use "(level)".
varname.label.sep
If varname.label = TRUE, you can change the separator to something other than = by specifying this parameter.

ia.space
When multiple axes are drawn for levels of interacting factors, the default is to group combinations related to a main effect. This is done by spacing the axes for the second to last of these within a group only 0.7 (by default) of the way down as compared with normal space of 1 unit.

tck
see tck under par
tcl
length of tick marks in nomogram
lmgp
spacing between numeric axis labels and axis (see par for mgp)
naxes
maximum number of axes to allow on one plot. If the nomogram requires more than one “page”, the “Points” axis will be repeated at the top of each page when necessary.

points.label
a character string giving the axis label for the points scale

total.points.label
a character string giving the axis label for the total points scale

total.sep.page
set to TRUE to force the total points and later axes to be placed on a separate page

total.fun
a user-provided function that will be executed before the total points axis is drawn. Default is not to execute a function. This is useful e.g. when total.sep.page = TRUE and you wish to use locator to find the coordinates for positioning an abbreviation legend before it’s too late and a new page is started (i.e., total.fun = function() print(locator(1))).
cap.labels
logical: should the factor labels have their first letter capitalized?

object
the result returned from nomogram

which
a character string giving the name of a variable for which to draw a legend with abbreviations of factor levels

y
y-coordinate to pass to the legend function. This is the upper left corner of the legend box. You can omit y if x is a list with named elements x and y. To use the mouse to locate the legend, specify locator(1) for x. For print, x is the result of nomogram.

ncol
the number of columns to form in drawing the legend.

Details
A variable is considered to be discrete if it is categorical or ordered or if datadist stored values for it (meaning it had <11 unique values). A variable is said to be indirectly related to another variable if the two are related by some interaction. For example, if a model has variables a, b, c, d, and the interactions are a:c and c:d, variable d is indirectly related to variable a. The complete list of variables related to a is c, d. If an axis is made for variable a, several axes will actually be drawn, one for each combination of c and d specified in interact.

Note that with a caliper, it is easy to continually add point scores for individual predictors, and then to place the caliper on the upper “Points” axis (with extrapolation if needed). Then transfer these points to the “Total Points” axis. In this way, points can be added without writing them down.
Confidence limits for an individual predictor score are really confidence limits for the entire linear predictor, with other predictors set to adjustment values. If \( lp = \text{TRUE} \), all confidence bars for all linear predictor values evaluated are drawn. The extent to which multiple confidence bars of differing widths appear at the same linear predictor value means that precision depended on how the linear predictor was arrived at (e.g., a certain value may be realized from a setting of a certain predictor that was associated with a large standard error on the regression coefficients for that predictor).

On occasion, you may want to reverse the regression coefficients of a model to make the “points” scales reverse direction. For parametric survival models, which are stated in terms of increasing regression effects meaning longer survival (the opposite of a Cox model), just do something like 

\[
\text{fit$coefficients} \leftarrow -\text{fit$coefficients}
\]

before invoking \text{nomogram}, and if you add function axes, negate the function arguments. For the Cox model, you also need to negate \text{fit$center}. If you omit \text{lp.at}, also negate \text{fit$linear.predictors}.

Value

a list of class "nomogram" that contains information used in plotting the axes. If you specified \text{abbrev = TRUE}, a list called abbrev is also returned that gives the abbreviations used for tick mark labels, if any. This list is useful for making legends and is used by \text{legend.nomabbrev} (see the last example). The returned list also has components called \text{total.points}, \text{lp}, and the function axis names. These components have components \text{x} (at argument vector given to axis), \text{y} (pos for axis), and \text{x.real}, the x-coordinates appearing on tick mark labels. An often useful result is stored in the list of data for each axis variable, namely the exact number of points that correspond to each tick mark on that variable’s axis.

npsurv

Nonparametric Survival Estimates for Censored Data

Description

Computes an estimate of a survival curve for censored data using either the Kaplan-Meier or the
Fleming-Harrington method or computes the predicted survivor function. For competing risks data
it computes the cumulative incidence curve. This calls the survival package’s survfit.formula
function. Attributes of the event time variable are saved (label and units of measurement).

For competing risks the second argument for Surv should be the event state variable, and it should
be a factor variable with the first factor level denoting right-censored observations.

Usage

npsurv(formula, data, subset, na.action, ...)

Arguments

formula          a formula object, which must have a Surv object as the response on the left of
the ~ operator and, if desired, terms separated by + operators on the right. One
of the terms may be a strata object. For a single survival curve the right hand
side should be ~ 1.

data,subset,na.action
    see survfit.formula

...                 see survfit.formula
Details

see `survfit.formula` for details

Value

an object of class "npsurv" and "survfit". See `survfit.object` for details. Methods defined for `survfit` objects are `print`, `summary`, `plot`, `lines`, and `points`.

Author(s)

Thomas Lumley <tlumley@u.washington.edu> and Terry Therneau

See Also

`survfit.cph` for survival curves from Cox models. `print`, `plot`, `lines`, `coxph`, `strata`, `survplot`

Examples

```r
require(survival)
# fit a Kaplan-Meier and plot it
fit <- npsurv(Surv(time, status) ~ x, data = aml)
plot(fit, lty = 2:3)
legend(100, .8, c("Maintained", "Nonmaintained"), lty = 2:3)

# Here is the data set from Turnbull
# There are no interval censored subjects, only left-censored (status=3),
# right-censored (status 0) and observed events (status 1)
#
# Time
# 1 2 3 4
#
# Type of observation
# death 12 6 2 3
# losses 3 2 0 3
# late entry 2 4 2 5
#
tdata <- data.frame(time = c(1,1,1,1,2,2,2,2,3,3,3,3,4,4,4),
                     status = rep(c(1,0,2),4),
                     n = c(12,3,2,6,2,4,2,0,2,3,3,5))
fit <- npsurv(Surv(time, time, status, type='interval') ~ 1,
              data=tdata, weights=n)

# Time to progression/death for patients with monoclonal gammopathy
# Competing risk curves (cumulative incidence)
m <- upData(mgus1, stop = stop / 365.25, units=c(stop='years'),
           labels=c(stop='Follow-up Time'), subset=start == 0)
f <- npsurv(Surv(stop, event) ~ 1, data=m)

# CI curves are always plotted from 0 upwards, rather than 1 down
plot(f, fun='event', xmax=20, mark.time=FALSE,
     col=2:3, xlab="Years post diagnosis of MGUS")
```
# Use survplot for enhanced displays of cumulative incidence curves for competing risks

```r
survplot(f, state='pcm', n.risk=TRUE, xlim=c(0, 20), ylim=c(0, .5), col=2)
survplot(f, state='death', add=TRUE, col=3)
```

```r
f <- npsurv(Surv(stop, event) ~ sex, data=m)
survplot(f, state='death', n.risk=TRUE, conf='diffbands')
```

## `ols`

### Linear Model Estimation Using Ordinary Least Squares

#### Description

Fits the usual weighted or unweighted linear regression model using the same fitting routines used by `lm`, but also storing the variance-covariance matrix `var` and using traditional dummy-variable coding for categorical factors. Also fits unweighted models using penalized least squares, with the same penalization options as in the `lrm` function. For penalized estimation, there is a fitter function `call lm.pfit`.

#### Usage

```r
ols(formula, data=environment(formula), weights, subset, na.action=na.delete,
    method="qr", model=FALSE,
    x=FALSE, y=FALSE, se.fit=FALSE, linear.predictors=TRUE,
    penalty=0, penalty.matrix, tol=1e-7, sigma,
    var.penalty=c('simple','sandwich'), ...)  
```

#### Arguments

- **formula**: an S formula object, e.g.
  
  `Y ~ rcs(x1,5)*lsp(x2,c(10,20))`

- **data**: name of an S data frame containing all needed variables. Omit this to use a data frame already in the S “search list”.

- **weights**: an optional vector of weights to be used in the fitting process. If specified, weighted least squares is used with weights `weights` (that is, minimizing `sum(w*e^2)`); otherwise ordinary least squares is used.

- **subset**: an expression defining a subset of the observations to use in the fit. The default is to use all observations. Specify for example `age>50 & sex="male"` or `c(1:100,200:300)` respectively to use the observations satisfying a logical expression or those having row numbers in the given vector.
na.action specifies an S function to handle missing data. The default is the function `na.delete`, which causes observations with any variable missing to be deleted. The main difference between `na.delete` and the S-supplied function `na.omit` is that `na.delete` makes a list of the number of observations that are missing on each variable in the model. The `na.action` is usually specified by e.g. `options(na.action="na.delete")`.

method specifies a particular fitting method, or "model.frame" instead to return the model frame of the predictor and response variables satisfying any subset or missing value checks.

model default is `FALSE`. Set to `TRUE` to return the model frame as element `model` of the fit object.

x default is `FALSE`. Set to `TRUE` to return the expanded design matrix as element `x` (without intercept indicators) of the returned fit object. Set both `x=TRUE` if you are going to use the `residuals` function later to return anything other than ordinary residuals.

y default is `FALSE`. Set to `TRUE` to return the vector of response values as element `y` of the fit.

se.fit default is `FALSE`. Set to `TRUE` to compute the estimated standard errors of the estimate of $X\beta$ and store them in element `se.fit` of the fit.

linear.predictors set to `FALSE` to cause predicted values not to be stored

penalty

penalty.matrix see `lrm`

tol tolerance for information matrix singularity

sigma If `sigma` is given, it is taken as the actual root mean squared error parameter for the model. Otherwise `sigma` is estimated from the data using the usual formulas (except for penalized models). It is often convenient to specify `sigma=1` for models with no error, when using `fastbw` to find an approximate model that predicts predicted values from the full model with a given accuracy.

var.penalty the type of variance-covariance matrix to be stored in the `var` component of the fit when penalization is used. The default is the inverse of the penalized information matrix. Specify `var.penalty="sandwich"` to use the sandwich estimator (see below under `var`), which limited simulation studies have shown yields variances estimates that are too low.

... arguments to pass to `lm.wfit` or `lm.fit`

Details

For penalized estimation, the penalty factor on the log likelihood is $-0.5\beta'P\beta/\sigma^2$, where $P$ is defined above. The penalized maximum likelihood estimate (penalized least squares or ridge estimate) of $\beta$ is $(X'X + P)^{-1}X'Y$. The maximum likelihood estimate of $\sigma^2$ is $(sse + \beta'P\beta)/n$, where `sse` is the sum of squared errors (residuals). The effective.df.diagonal vector is the diagonal of the matrix $X'X/(sse/n)\sigma^2(X'X + P)^{-1}$. 
Value

the same objects returned from lm (unless penalty or penalty.matrix are given - then an abbreviated list is returned since lm.pfit is used as a fitter) plus the design attributes (see rms). Predicted values are always returned, in the element linear.predictors. The vectors or matrix stored if y=TRUE or x=TRUE have rows deleted according to subset and to missing data, and have names or row names that come from the data frame used as input data. If penalty or penalty.matrix is given, the var matrix returned is an improved variance-covariance matrix for the penalized regression coefficient estimates. If var.penalty="sandwich" (not the default, as limited simulation studies have found it provides variance estimates that are too low) it is defined as $\sigma^2(X'X + P)^{-1}X'X(X'X + P)^{-1}$, where $P$ is penalty factors * penalty.matrix, with a column and row of zeros added for the intercept. When var.penalty="simple" (the default), var is $\sigma^2(X'X + P)^{-1}$. The returned list has a vector stats with named elements n, Model L.R., d.f., R2, g, Sigma. Model L.R. is the model likelihood ratio $\chi^2$ statistic, and R2 is $R^2$. For penalized estimation, d.f. is the effective degrees of freedom, which is the sum of the elements of another vector returned, effective.df.diagonal, minus one for the intercept. g is the $g$-index. Sigma is the penalized maximum likelihood estimate (see below).

** orm  
**Ordinal Regression Model**

**Description**

Fits ordinal cumulative probability models for continuous or ordinal response variables, efficiently allowing for a large number of intercepts by capitalizing on the information matrix being sparse. Five different distribution functions are implemented, with the default being the logistic (i.e., the proportional odds model). The ordinal cumulative probability models are stated in terms of exceedance probabilities \( \text{Prob}[Y \geq y|X] \) so that as with OLS larger predicted values are associated with larger \( y \). This is important to note for the asymmetric distributions given by the log-log and complementary log-log families, for which negating the linear predictor does not result in \( \text{Prob}[Y < y|X] \). The family argument is defined in `orm.fit`. The model assumes that the inverse of the assumed cumulative distribution function, when applied to one minus the true cumulative distribution function and plotted on the \( y \)-axis (with the original \( y \) on the \( x \)-axis) yields parallel curves (though not necessarily linear). This can be checked by plotting the inverse cumulative probability function of one minus the empirical distribution function, stratified by \( X \), and assessing parallelism. Note that parametric regression models make the much stronger assumption of linearity of such inverse functions.

For the `print` method, format of output is controlled by the user previously running `options(prType="lang")` where `lang` is "plain" (the default), "latex", or "html".

`Quantile.orm` creates an R function that computes an estimate of a given quantile for a given value of the linear predictor (which was assumed to use the first intercept). It uses a linear interpolation method by default, but you can override that to use a discrete method by specifying `method="discrete"` when calling the function generated by `Quantile`. Optionally a normal approximation for a confidence interval for quantiles will be computed using the delta method, if `conf.int > 0` is specified to the function generated from calling `Quantile` and you specify \( X \). In that case, a "lims" attribute is included in the result computed by the derived quantile function.
Usage

orm(formula, data=environment(formula),
    subset, na.action=na.delete, method="orm.fit",
    model=FALSE, x=FALSE, y=FALSE, linear.predictors=TRUE, se.fit=FALSE,
    penalty=0, penalty.matrix, tol=1e-7, eps=0.005,
    var.penalty=c('simple','sandwich'), scale=FALSE, ...)

## S3 method for class 'orm'
print(x, digits=4, r2=c(0,2,4), coefs=TRUE, pg=FALSE,
    intercepts=x$non.slopes < 10, title, ...)

## S3 method for class 'orm'
Quantile(object, codes=FALSE, ...)

Arguments

formula a formula object. An offset term can be included. The offset causes fitting
of a model such as logit(Y = 1) = Xβ + W, where W is the offset variable
having no estimated coefficient. The response variable can be any data type;
orm converts it in alphabetic or numeric order to a factor variable and recodes it
1,2,... internally.

data data frame to use. Default is the current frame.
subset logical expression or vector of subscripts defining a subset of observations to
analyze

na.action function to handle NAs in the data. Default is na.delete, which deletes any
observation having response or predictor missing, while preserving the attributes
of the predictors and maintaining frequencies of deletions due to each variable in
the model. This is usually specified using options(na.action="na.delete").

method name of fitting function. Only allowable choice at present is orm.fit.

model causes the model frame to be returned in the fit object

x causes the expanded design matrix (with missings excluded) to be returned under
the name x. For print, an object created by orm.

y causes the response variable (with missings excluded) to be returned under the
name y.

linear.predictors causes the predicted X beta (with missings excluded) to be returned under
the name linear.predictors. The first intercept is used.

se.fit causes the standard errors of the fitted values (on the linear predictor scale) to
be returned under the name se.fit. The middle intercept is used.

penalty see lrm

penalty.matrix see lrm

tol singularity criterion (see orm.fit)

eps difference in −2log likelihood for declaring convergence

var.penalty see lrm
scale

Set to TRUE to subtract column means and divide by column standard deviations of the design matrix before fitting, and to back-solve for the un-normalized covariance matrix and regression coefficients. This can sometimes make the model converge for very large sample sizes where for example spline or polynomial component variables create scaling problems leading to loss of precision when accumulating sums of squares and crossproducts.

Arguments that are passed to `orm.fit`, or from `print`, to `prModFit`. Ignored for `Quantile`. One of the most important arguments is `family`.

digits

Number of significant digits to use.

r2

Vector of integers specifying which $R^2$ measures to print, with 0 for Nagelkerke $R^2$ and 1:4 corresponding to the 4 measures computed by `R2Measures`. Default is to print Nagelkerke (labeled R2) and second and fourth `R2Measures` which are the measures adjusted for the number of predictors, first for the raw sample size then for the effective sample size, which here is from the formula for the approximate variance of a log odds ratio in a proportional odds model.

pg

Set to TRUE to print g-indexes.

coefs

Specify coefs=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.

intercepts

By default, intercepts are only printed if there are fewer than 10 of them. Otherwise this is controlled by specifying intercepts=FALSE or TRUE.

title

A character string title to be passed to `prModFit`. Default is constructed from the name of the distribution family.

object

An object created by `orm`.

codes

If TRUE, uses the integer codes 1, 2, ..., k for the k-level response in computing the predicted quantile.

Value

The returned fit object of `orm` contains the following components in addition to the ones mentioned under the optional arguments.

call

Calling expression.

freq

Table of frequencies for Y in order of increasing Y.

stats

Vector with the following elements: number of observations used in the fit, number of unique Y values, median Y from among the observations used in the fit, maximum absolute value of first derivative of log likelihood, model likelihood ratio $\chi^2$, d.f., $P$-value, score $\chi^2$ statistic (if no initial values given), $P$-value, Spearman’s $\rho$ rank correlation between the linear predictor and Y, the Nagelkerke $R^2$ index, $R^2$ indexes computed by `R2Measures`, the g-index, $gr$ (the $g$-index on the odds ratio scale), and $pdm$ (the mean absolute difference between 0.5 and the predicted probability that $Y \geq$ the marginal median). In the case of penalized estimation, the "Model L.R." is computed without the penalty factor, and "$d.f.$" is the effective d.f. from Gray’s (1992) Equation 2.9. The $P$-value uses this corrected model L.R. $\chi^2$ and corrected d.f. The score chi-square statistic uses first derivatives which contain penalty components.

#2 0.0 50 0.0515 0.0635 0.0615 0.060 0.0620 0.0620 0.0620
**Description**

Fits ordinal cumulative probability models for continuous or ordinal response variables, efficiently allowing for a large number of intercepts by capitalizing on the information matrix being sparse. Five different distribution functions are implemented, with the default being the logistic (yielding the proportional odds model). Penalized estimation will be implemented in the future. Weights are not implemented. The optimization method is Newton-Raphson with step-halving. Execution time is linear in the number of intercepts.

**Usage**

```r
orm.fit(x=NULL, y, family="logistic", offset=0., initial, maxit=12L, eps=.005, tol=1e-7, trace=FALSE, penalty.matrix=NULL, scale=FALSE)
```

**Arguments**

- `x` design matrix with no column for an intercept
- `y` response vector, numeric, factor, or character. The ordering of levels is assumed from `factor(y)`.
- `family` the distribution family, corresponding to logistic (the default), Gaussian, Cauchy, Gumbel maximum \( \exp(-\exp(-x)) \); extreme value type I, and Gumbel minimum \( 1 - \exp(-\exp(x)) \) distributions. These are the cumulative distribution functions assumed for \( \Pr(Y \geq y|X) \). The family argument can be an unquoted or a quoted string, e.g. `family=loglog` or `family="loglog"`. To use a built-in family, the string must be one of the following corresponding to the previous list: logistic, probit, loglog, cloglog, cauchit. The user can also provide her own customized family by setting `family` to a list with elements `cumprob`, `inverse`, `deriv`, `deriv2`; see the body of `orm.fit` for examples. An additional element, `name` must be given, which is a character string used to name the family for print and latex.
- `offset` optional numeric vector containing an offset on the logit scale
- `initial` vector of initial parameter estimates, beginning with the intercepts. If `initial` is not specified, the function computes the overall score \( \chi^2 \) test for the global null hypothesis of no regression.
- `maxit` maximum no. iterations (default=12).
eps  difference in \(-2\log\) likelihood for declaring convergence. Default is .005. If the \(-2\log\) likelihood gets worse by \(\text{eps}/10\) while the maximum absolute first derivative of 
\[-2 \log\]
likelihood is below 1E-9, convergence is still declared. This handles the case where the initial estimates are MLEs, to prevent endless step-halving.
tol  Singularity criterion. Default is 1e-7
trace  set to \text{TRUE} to print -2 log likelihood, step-halving fraction, change in -2 log likelihood, and maximum absolute value of first derivative at each iteration.
penalty.matrix  a self-contained ready-to-use penalty matrix - see \text{lrm}
scale  set to \text{TRUE} to subtract column means and divide by column standard deviations of \(x\) before fitting, and to back-solve for the un-normalized covariance matrix and regression coefficients. This can sometimes make the model converge for very large sample sizes where for example spline or polynomial component variables create scaling problems leading to loss of precision when accumulating sums of squares and crossproducts.

Value

a list with the following components:
call  calling expression
freq  table of frequencies for \(y\) in order of increasing \(y\)
yunique  vector of sorted unique values of \(y\)
stats  vector with the following elements: number of observations used in the fit, number of unique \(y\) values, median \(y\) from among the observations used in the fit, maximum absolute value of first derivative of log likelihood, model likelihood ratio chi-square, d.f., P-value, score chi-square and its P-value, Spearman’s \(\rho\) rank correlation between linear predictor and \(y\), the Nagelkerke \(R^2\) index, the \(g\)-index, \(gr\) (the \(g\)-index on the ratio scale), and \(pdm\) (the mean absolute difference between 0.5 and the estimated probability that \(y \geq \) the marginal median). When \text{penalty.matrix} is present, the \(\chi^2\), d.f., and P-value are not corrected for the effective d.f.
fail  set to \text{TRUE} if convergence failed (and \text{maxit}>1)
coefficients  estimated parameters
var  estimated variance-covariance matrix (inverse of information matrix). Note that in the case of penalized estimation, \(var\) is not the improved sandwich-type estimator (which \text{lrm} does compute). The only intercept parameter included in the stored object is the middle intercept.
family, trans  see \text{orm}
deviance  \(-2\log\) likelihoods. When an offset variable is present, three deviances are computed: for intercept(s) only, for intercepts+offset, and for intercepts+offset+predictors. When there is no offset variable, the vector contains deviances for the intercept(s)-only model and the model with intercept(s) and predictors.
non.slopes  number of intercepts in model
interceptRef  the index of the middle (median) intercept used in computing the linear predictor
and var
linear.predictors  the linear predictor using the first intercept
penalty.matrix  see above
info.matrix  see orm

pentrace  Trace AIC and BIC vs. Penalty

Description

For an ordinary unpenalized fit from lrm or ols and for a vector or list of penalties, fits a series of logistic or linear models using penalized maximum likelihood estimation, and saves the effective degrees of freedom, Akaike Information Criterion (AIC), Schwarz Bayesian Information Criterion (BIC), and Hurvich and Tsai’s corrected AIC (AICc). Optionally pentrace can use the nlminb function to solve for the optimum penalty factor or combination of factors penalizing different kinds of terms in the model. The effective.df function prints the original and effective degrees of freedom for a penalized fit or for an unpenalized fit and the best penalization determined from a previous invocation of pentrace if method="grid" (the default). The effective d.f. is computed separately for each class of terms in the model (e.g., interaction, nonlinear). A plot method exists to plot the results, and a print method exists to print the most pertinent components. Both AIC and BIC may be plotted if there is only one penalty factor type specified in penalty. Otherwise, the first two types of penalty factors are plotted, showing only the AIC.
Usage

pentrace(fit, penalty, penalty.matrix,
method=c('grid','optimize'),
which=c('aic.c','aic','bic'), target.df=NULL,
fitter, pr=FALSE, tol=1e-7,
keep.coef=FALSE, complex.more=TRUE, verbose=FALSE, maxit=12,
subset, noaddzero=FALSE)

effective.df(fit, object)

## S3 method for class 'pentrace'
print(x, ...)

## S3 method for class 'pentrace'
plot(x, method=c('points','image'),
which=c('effective.df','aic','aic.c','bic'), pch=2, add=FALSE,
ylim, ...)

Arguments

- **fit**: a result from lrm or ols with x=TRUE, y=TRUE and without using penalty or penalty.matrix (or optionally using penalization in the case of effective.df)
- **penalty**: can be a vector or a list. If it is a vector, all types of terms in the model will be penalized by the same amount, specified by elements in penalty, with a penalty of zero automatically added. penalty can also be a list in the format documented in the lrm function, except that elements of the list can be vectors. The expand.grid function is invoked by pentrace to generate all possible combinations of penalties. For example, specifying penalty=list(simple=1:2, nonlinear=1:3) will generate 6 combinations to try, so that the analyst can attempt to determine whether penalizing more complex terms in the model more than the linear or categorical variable terms will be beneficial. If complex.more=TRUE, it is assumed that the variables given in penalty are listed in order from less complex to more complex. With method="optimize" penalty specifies an initial guess for the penalty or penalties. If all term types are to be equally penalized, penalty should be a single number, otherwise it should be a list containing single numbers as elements, e.g., penalty=list(simple=1, nonlinear=2). Experience has shown that the optimization algorithm is more likely to find a reasonable solution when the starting value specified in penalty is too large rather than too small.
- **object**: an object returned by pentrace. For effective.df, object can be omitted if the fit was penalized.
- **penalty.matrix**: see lrm
- **method**: The default is method="grid" to print various indexes for all combinations of penalty parameters given by the user. Specify method="optimize" to have pentrace use nlmirb to solve for the combination of penalty parameters that gives the maximum value of the objective named in which, or, if target.df is given, to find the combination that yields target.df effective total degrees.
of freedom for the model. When target.df is specified, method is set to "optimize" automatically. For plot.pentrace this parameter applies only if more than one penalty term-type was used. The default is to use open triangles whose sizes are proportional to the ranks of the AICs, plotting the first two penalty factors respectively on the x and y axes. Use method="image" to plot an image plot.

which the objective to maximize for either method. Default is "aic.c" (corrected AIC). For plot.pentrace, which is a vector of names of criteria to show; default is to plot all 4 types, with effective d.f. in its own separate plot

target.df applies only to method="optimize". See method. target.df makes sense mainly when a single type of penalty factor is specified.
fitter a fitting function. Default is lrm.fit (lm.pfit is always used for ols).
pr set to TRUE to print intermediate results
tol tolerance for declaring a matrix singular (see lrm.fit, solvet)
keep.coef set to TRUE to store matrix of regression coefficients for all the fits (corresponding to increasing values of penalty) in object Coefficients in the returned list. Rows correspond to penalties, columns to regression parameters.
complex.more By default if penalty is a list, combinations of penalties for which complex terms are penalized less than less complex terms will be dropped after expand.grid is invoked. Set complex.more=FALSE to allow more complex terms to be penalized less. Currently this option is ignored for method="optimize".
verbose set to TRUE to print number of intercepts and sum of effective degrees of freedom
maxit maximum number of iterations to allow in a model fit (default=12). This is passed to the appropriate fitter function with the correct argument name. Increase maxit if you had to when fitting the original unpenalized model.
subset a logical or integer vector specifying rows of the design and response matrices to subset in fitting models. This is most useful for bootstrapping pentrace to see if the best penalty can be estimated with little error so that variation due to selecting the optimal penalty can be safely ignored when bootstrapping standard errors of regression coefficients and measures of predictive accuracy. See an example below.
noaddzero set to TRUE to not add an unpenalized model to the list of models to fit
x a result from pentrace
pch used for method="points"
add set to TRUE to add to an existing plot. In that case, the effective d.f. plot is not re-drawn, but the AIC/BIC plot is added to.
ylim 2-vector of y-axis limits for plots other than effective d.f.
... other arguments passed to plot, lines, or image

Value
da list of class "pentrace" with elements penalty, df, objective, fit, var.adj, diag, results.all, and optionally Coefficients. The first 6 elements correspond to the fit that had the best objective as named in the which argument, from the sequence of fits tried. Here fit is the fit object
from fitter which was a penalized fit, diag is the diagonal of the matrix used to compute the effective d.f., and var.adj is Gray (1992) Equation 2.9, which is an improved covariance matrix for the penalized beta. results.all is a data frame whose first few variables are the components of penalty and whose other columns are df, aic, bic, aic.c. results.all thus contains a summary of results for all fits attempted. When method="optimize", only two components are returned: penalty and objective, and the object does not have a class.

cholesterol <- rnorm(n, 200, 25)
sex <- factor(sample(c("female","male"), n,TRUE))
# Specify population model for log odds that Y=1
L <- .4*(sex=="male") + .045*(age-50) +
   (log(cholesterol - 10)-5.2)*(-2*(sex=="female") + 2*(sex=="male"))
# Simulate binary y to have Prob(y=1) = 1/[1+exp(-L)]
y <- ifelse(runif(n) < plogis(L), 1, 0)

f <- lrm(y ~ blood.pressure + sex * (age + rcs(cholesterol,4)), x=TRUE, y=TRUE)
p <- pentrace(f, seq(.2,1,by=.05))
plot(p)
p$diag  # may learn something about fractional effective d.f.
# for each original parameter
pentrace(f, list(simple=c(0,.2,.4), nonlinear=c(0,.2,.4,.8,1)))

# Bootstrap pentrace 5 times, making a plot of corrected AIC plot with 5 reps
n <- nrow(f$x)
```r
plot(pentrace(f, seq(.2,1,by=.05)), which='aic.c',
     col=1, ylim=c(30,120)) # original in black
for(j in 1:5)
  plot(pentrace(f, seq(.2,1,by=.05), subset=sample(n,n,TRUE)),
        which='aic.c', col=j+1, add=TRUE)

# Find penalty giving optimum corrected AIC. Initial guess is 1.0
# Not implemented yet
# pentrace(f, 1, method='optimize')

# Find penalty reducing total regression d.f. effectively to 5
# pentrace(f, 1, target.df=5)

# Re-fit with penalty giving best aic.c without differential penalization
f <- update(f, penalty=p$penalty)
effective.df(f)
```

---

### Description

Plot Bayesian Contrast Posterior Densities

### Usage

```r
## S3 method for class 'contrast.rms'
plot(
    x, 
    bivar = FALSE, 
    bivarmethod = c("ellipse", "kernel"), 
    prob = 0.95, 
    which = c("both", "diff", "ind"), 
    nrow = NULL, 
    ncol = NULL, 
    ...
)
```

### Arguments

- **x**: the result of `contrast.rms`
- **bivar**: set to `TRUE` to plot 2-d posterior density contour
- **bivarmethod**: see `rmsb::pdensityContour()`
- **prob**: posterior coverage probability for HPD interval or 2-d contour
which applies when plotting the result of `contrast(..., fun=)`, defaulting to showing the posterior density of both estimates plus their difference. Set to "ind" to only show the two individual densities or "diff" to only show the posterior density for the differences.

`nrow` for `ggplot2::facet_wrap()`

`ncol` likewise

... unused

Details

If there are exactly two contrasts and `bivar=TRUE` plots an elliptical or kernal (based on `bivarmethod` posterior density contour with probability `prob`). Otherwise plots a series of posterior densities of contrasts along with HPD intervals, posterior means, and medians. When the result being plotted comes from `contrast` with `fun=` specified, both the two individual estimates and their difference are plotted.

Value

ggplot2 object

Author(s)

Frank Harrell

plot.Predict

Plot Effects of Variables Estimated by a Regression Model Fit

Description

Uses lattice graphics to plot the effect of one or two predictors on the linear predictor or X beta scale, or on some transformation of that scale. The first argument specifies the result of the `Predict` function. The predictor is always plotted in its original coding. `plot.Predict` uses the `xyplot` function unless `formula` is omitted and the x-axis variable is a factor, in which case it reverses the x- and y-axes and uses the `Dotplot` function.

If `data` is given, a rug plot is drawn showing the location/density of data values for the x-axis variable. If there is a `groups` (superposition) variable that generated separate curves, the data density specific to each class of points is shown. This assumes that the second variable was a factor variable. The rug plots are drawn by `scat1d`. When the same predictor is used on all x-axes, and multiple panels are drawn, you can use `subdata` to specify an expression to subset according to other criteria in addition.

To plot effects instead of estimates (e.g., treatment differences as a function of interacting factors) see `contrast.rms` and `summary.rms`.

`pantext` creates a lattice panel function for including text such as that produced by `print.anova.rms` inside a panel or in a base graphic.
Usage

## S3 method for class 'Predict'
plot(x, formula, groups=NULL,
    cond=NULL, varypred=FALSE, subset,
    xlim, ylim, xlab, ylab,
    data=NULL, subdata, anova=NULL, pval=FALSE, cex.anova=.85,
    col.fill=gray(seq(.825, .55, length=5)),
    adj.subtitle, cex.adj, cex.axis, perim=NULL, digits=4, nlevels=3,
    nlines=FALSE, addpanel, scat1d.opts=list(frac=0.025, lwd=0.3),
    type=NULL, yscale=NULL, scaletrans=function(z) z, ...)

pantext(object, x, y, cex=.5, adj=0, fontfamily="Courier", lattice=TRUE)

Arguments

x
a data frame created by predict, or for pantext the x-coordinate for text

formula
the right hand side of a lattice formula reference variables in data frame x.
You may not specify formula if you varied multiple predictors separately when
calling Predict. Otherwise, when formula is not given, plot.Predict const-
structs one from information in x.

groups
an optional name of one of the variables in x that is to be used as a grouping
(superpositioning) variable. Note that groups does not contain the groups data
as is customary in lattice; it is only a single character string specifying the
name of the grouping variable.

cond
when plotting effects of different predictors, cond is a character string that spec-
ifies a single variable name in x that can be used to form panels. Only applies if
using rbind to combine several Predict results.

varypred
set to TRUE if x is the result of passing multiple Predict results, that repre-
sent different predictors, to rbind.Predict. This will cause the .set. variable
created by rbind to be copied to the .predictor. variable.

subset
a subsetting expression for restricting the rows of x that are used in plotting. For
example, predictions may have been requested for males and females but one
wants to plot only females.

xlim
This parameter is seldom used, as limits are usually controlled with Predict.
One reason to use xlim is to plot a factor variable on the x-axis that was cre-
ated with the cut2 function with the levels.mean option, with val.lev=TRUE
specified to plot.Predict. In this case you may want the axis to have the range
of the original variable values given to cut2 rather than the range of the means
within quantile groups.

ylim
Range for plotting on response variable axis. Computed by default.

xlab
Label for x-axis. Default is one given to asis, rcs, etc., which may have been
the "label" attribute of the variable.

ylab
Label for y-axis. If fun is not given, default is "log Odds" for lrm, "log
Relative Hazard" for cph, name of the response variable for ols, TRUE or
log(TRUE) for psm, or "X * Beta" otherwise.
data

A data frame containing the original raw data on which the regression model was based, or at least containing the x-axis and grouping variable. If data is present and contains the needed variables, the original data are added to the graph in the form of a rug plot using `scat1d`.

subdata

If data is specified, an expression to be evaluated in the data environment that evaluates to a logical vector specifying which observations in data to keep. This will be intersected with the criterion for the groups variable. Example: if conditioning on two paneling variables using `|a*b` you can specify `subdata=b==levels(b)[which.packet()]`, where the 2 comes from the fact that b was listed second after the vertical bar (this assumes b is a factor in data. Another example: `subdata=sex==c('male','female')[current.row()]`.

anova

An object returned by `anova.rms`. If anova is specified, the overall test of association for predictor plotted is added as text to each panel, located at the spot at which the panel is most empty unless there is significant empty space at the top or bottom of the panel; these areas are given preference.

digits

Controls how numeric variables used for panel labels are formatted. The default is 4 significant digits.

nlevels

When groups and formula are not specified, if any panel variable has nlevels or fewer values, that variable is converted to a groups (superpositioning) variable. Set nlevels=0 to prevent this behavior. For other situations, a numeric x-axis variable with nlevels or fewer unique values will cause a dot plot to be drawn instead of an x-y plot.

nlines

If formula is given, you can set nlines to `TRUE` to convert the x-axis variable to a factor and then to an integer. Points are plotted at integer values on the x-axis but labeled with category levels. Points are connected by lines.

addpanel

An additional panel function to call along with panel functions used for `xyplot` and `Dotplot` displays.
plot.Predict

scat1d.opts     a list containing named elements that specifies parameters to scat1d when data is given. The col parameter is usually derived from other plotting information and not specified by the user.

type            a value ("1", "p", "b") to override default choices related to showing or connecting points. Especially useful for discrete x coordinate variables.

yscale          a lattice scale list for the y-axis to be added to what is automatically generated for the x-axis. Example: yscale=list(at=c(.005,.01,.05),labels=format(c(.005,.01,.05)).

See xyplot

scaletrans      a function that operates on the scale object created by plot.Predict to produce a modified scale object that is passed to the lattice graphics function. This is useful for adding other scales options or for changing the x-axis limits for one predictor.

... extra arguments to pass to xYplot or Dotplot. Some useful ones are label.curves and abline. Set label.curves to FALSE to suppress labeling of separate curves. Default is TRUE, which causes labcurve to be invoked to place labels at positions where the curves are most separated, labeling each curve with the full curve label. Set label.curves to a list to specify options to labcurve, e.g., label.curves= list(method="arrow",cex=.8). These option names may be abbreviated in the usual way arguments are abbreviated. Use for example label.curves=list(keys=letters[1:5]) to draw single lower case letters on 5 curves where they are most separated, and automatically position a legend in the most empty part of the plot. The col, lty, and lwd parameters are passed automatically to labcurve although they may be overridden here. It is also useful to use ...to pass lattice graphics parameters, e.g. par.settings=list(axis.text=list(cex=1.2), par.ylab.text=list(col='blue',cex=.9),par...

object          an object having a print method

xy              y-coordinate for placing text in a lattice panel or on a base graphics plot

cex             character expansion size for pantext

adj             text justification. Default is left justified.

fontfamily      font family for pantext. Default is "Courier" which will line up columns of a table.

lattice         set to FALSE to use text instead of ltext in the function generated by pantext, to use base graphics

Details

When a groups (superpositioning) variable was used, you can issue the command Key(...) after printing the result of plot.Predict, to draw a key for the groups.

Value

a lattice object ready to print for rendering.

Note

If plotting the effects of all predictors you can reorder the panels using for example p <- Predict(fit);
p$.predictor. <- factor(p$.predictor., v) where v is a vector of predictor names specified in the desired order.

plot.xmean.ordinaly  
Plot Mean X vs. Ordinal Y

Description

Separately for each predictor variable $X$ in a formula, plots the mean of $X$ vs. levels of $Y$. Then under the proportional odds assumption, the expected value of the predictor for each $Y$ value is also plotted (as a dotted line). This plot is useful for assessing the ordinality assumption for $Y$ separately for each $X$, and for assessing the proportional odds assumption in a simple univariable way. If several predictors do not distinguish adjacent categories of $Y$, those levels may need to be pooled. This display assumes that each predictor is linearly related to the log odds of each event in the proportional odds model. There is also an option to plot the expected means assuming a forward continuation ratio model.

Usage

## S3 method for class 'xmean.ordinaly'
plot(x, data, subset, na.action, subn=TRUE,
    cr=FALSE, topcats=1, cex.points=.75, ...)

Arguments

x  an S formula. Response variable is treated as ordinal. For categorical predictors, a binary version of the variable is substituted, specifying whether or not the variable equals the modal category. Interactions or non-linear effects are not allowed.
data  a data frame or frame number
subset  vector of subscripts or logical vector describing subset of data to analyze
na.action  defaults to na.keep so all NAs are initially retained. Then NAs are deleted only for each predictor currently being plotted. Specify na.action=na.delete to remove observations that are missing on any of the predictors (or the response).
subn  set to FALSE to suppress a left bottom subtitle specifying the sample size used in constructing each plot
cr

set to TRUE to plot expected values by levels of the response, assuming a forward continuation ratio model holds. The function is fairly slow when this option is specified.

topcats

When a predictor is categorical, by default only the proportion of observations in the overall most frequent category will be plotted against response variable strata. Specify a higher value of topcats to make separate plots for the proportion in the k most frequent predictor categories, where k is \( \text{min} \{ \text{ncat}-1, \text{topcats} \} \) and ncat is the number of unique values of the predictor.

cex.points

if cr is TRUE, specifies the size of the "C" that is plotted. Default is 0.75.

... other arguments passed to plot and lines

# Simulate data from a population proportional odds model
set.seed(1)
n <- 400
age <- rnorm(n, 50, 10)
blood.pressure <- rnorm(n, 120, 15)
region <- factor(sample(c('north','south','east','west'), n, replace=TRUE))
L <- .2*(age-50) + .1*(blood.pressure-120)
p12 <- plogis(L)  # Pr(Y>=1)
p2 <- plogis(L-1)  # Pr(Y=2)
p <- cbind(1-p12, p12-p2, p2)  # individual class probabilites
# Cumulative probabilities:
cp <- matrix(cumsum(t(p)) - rep(0:(n-1), rep(3,n)), byrow=TRUE, ncol=3)
y <- (cp < runif(n)) %*% rep(1,3)
# Thanks to Dave Krantz <dhk@paradox.psych.columbia.edu> for this trick
par(mfrow=c(2,2))
plot.xmean.ordinaly(y ~ age + blood.pressure + region, cr=TRUE, topcats=2)
```
par(mfrow=c(1,1))
# Note that for unimportant predictors we don't care very much about the
# shapes of these plots. Use the Hmisc chiSquare function to compute
# Pearson chi-square statistics to rank the variables by unadjusted
# importance without assuming any ordering of the response:
chiSquare(y ~ age + blood.pressure + region, g=3)
chiSquare(y ~ age + blood.pressure + region, g=5)

plotp.Predict

Plot Effects of Variables Estimated by a Regression Model Fit Using
plotly

Description

Uses plotly graphics (without using ggplot2) to plot the effect of one or two predictors on the linear predictor or X beta scale, or on some transformation of that scale. The first argument specifies the result of the Predict function. The predictor is always plotted in its original coding. Hover text shows point estimates, confidence intervals, and on the leftmost x-point, adjustment variable settings.

If Predict was run with no variable settings, so that each predictor is varied one at a time, the result of plotp.Predict is a list with two elements. The first, named Continuous, is a plotly object containing a single graphic with all the continuous predictors varying. The second, named Categorical, is a plotly object containing a single graphic with all the categorical predictors varying. If there are no categorical predictors, the value returned by by plotp.Predict is a single plotly object and not a list of objects.

If rdata is given, a spike histogram is drawn showing the location/density of data values for the x-axis variable. If there is a superposition variable that generated separate curves, the data density specific to each class of points is shown. The histograms are drawn by histSpikeg.

To plot effects instead of estimates (e.g., treatment differences as a function of interacting factors) see contrast.rms and summary.rms.

Unlike ggplot.Predict, plotp.Predict does not handle groups, anova, or perim arguments.

Usage

## S3 method for class 'Predict'
plotp(data, subset, xlim, ylim, xlab, ylab,
    rdata=NULL, nlevels=3, vnames=c('labels','names'),
    histSpike.opts=list(frac=function(f) 0.01 +
    0.02 * sqrt(f - 1)/sqrt(max(f, 2) - 1), side=1, nint=100),
    n.cols=3, width=800, ...)

Arguments

data a data frame created by Predict
subset a subsetting expression for restricting the rows of data that are used in plotting.
For example, predictions may have been requested for males and females but one wants to plot only females.
plotp.Predict

xlim ignored unless predictors were specified to Predict. Specifies the x-axis limits
of the single plot produced.

ylim Range for plotting on response variable axis. Computed by default and includes
the confidence limits.

xlab Label for x-axis when a single plot is made, i.e., when a predictor is specified
to Predict. Default is one given to asis, rcs, etc., which may have been the
"label" attribute of the variable.

ylab Label for y-axis. If fun is not given, default is "log Odds" for lrm, "log
Relative Hazard" for cph, name of the response variable for ols, TRUE or
log(TRUE) for psm, or "X * Beta" otherwise. Specify ylab=NULL to omit y-axis
labels.

rdata a data frame containing the original raw data on which the regression model
were based, or at least containing the x-axis and grouping variable. If rdata
is present and contains the needed variables, the original data are added to the
graph in the form of a spike histogram using histSpike in the Hmisc package.

nlevels A non-numeric x-axis variable with nlevels or fewer unique values will cause
a horizontal dot plot to be drawn instead of an x-y plot.

vnames applies to the case where multiple plots are produced separately by predictor.
Set to 'names' to use variable names instead of labels for these small plots.

histSpike.opts a list containing named elements that specifies parameters to histSpike when
rdata is given. The col parameter is usually derived from other plotting inform-
ation and not specified by the user.

ncols number of columns of plots to use when plotting multiple continuous predictors

width width in pixels for plotly graphics

... ignored

Value

a plotly object or a list containing two elements, each one a plotly object

**poma**

*Examine proportional odds and parallelism assumptions of 'orm' and 'lrm' model fits.*

**Description**

Based on codes and strategies from Frank Harrell's canonical 'Regression Modeling Strategies' text

**Usage**

```r
poma(mod.orm, cutval)
```

**Arguments**

- **mod.orm**: Model fit of class 'orm' or 'lrm'. For 'fit.mult.impute' objects, 'poma' will refit model on a singly-imputed data-set
- **cutval**: Numeric vector; sequence of observed values to cut outcome

**Details**

- **Strategy 1**: Apply different link functions to Prob of Binary Ys (defined by cutval). Regress transformed outcome on combined X and assess constancy of slopes (betas) across cut-points
- **Strategy 2**: Generate score residual plot for each predictor (for response variable with <10 unique levels)
- **Strategy 3**: Assess parallelism of link function transformed inverse CDFs curves for different XBeta levels (for response variables with >=10 unique levels)

**Author(s)**

Yong Hao Pua <puayonghao@gmail.com>

pphsm

Parametric Proportional Hazards form of AFT Models

Description

Translates an accelerated failure time (AFT) model fitted by psm to proportional hazards form, if the fitted model was a Weibull or exponential model (extreme value distribution with "log" link).

Usage

pphsm(fit)
## S3 method for class 'pphsm'
print(x, digits=max(options()$digits - 4, 3),
correlation=TRUE, ...)
## S3 method for class 'pphsm'
vcov(object, ...)

Arguments

fit
  fit object created by psm
x
  result of psm
digits
  how many significant digits are to be used for the returned value
correlation
  set to FALSE to suppress printing of correlation matrix of parameter estimates
...
  ignored
object
  a pphsm object
predab.resample

Predictive Ability using Resampling

Description

predab.resample is a general-purpose function that is used by functions for specific models. It computes estimates of optimism of, and bias-corrected estimates of a vector of indexes of predictive accuracy, for a model with a specified design matrix, with or without fast backward step-down of predictors. If bw=TRUE, the design matrix x must have been created by ols, lrm, or cph. If bw=TRUE, predab.resample stores as the kept attribute a logical matrix encoding which factors were selected at each repetition.

Usage

predab.resample(fit.orig, fit, measure,
    method=c("boot","crossvalidation",".632","randomization"),
    bw=FALSE, B=50, pr=FALSE, prmodel=TRUE,
    rule="aic", type="residual", sls=.05, aics=0,
    tol=1e-12, force=NULL, estimates=TRUE,
    non.slopes.in.x=TRUE, kint=1,
    cluster, subset, group=NULL,
    allow.varying.intercepts=FALSE, debug=FALSE, ...)

Value

a new fit object with transformed parameter estimates

Author(s)

Frank Harrell
Department of Biostatistics
Vanderbilt University

psm, summary.rms, print.pphsm

Examples

set.seed(1)
S <- Surv(runif(100))
x <- runif(100)
dd <- datadist(x); options(datadist='dd')
f <- psm(S ~ x, dist="exponential")
summary(f)       # effects on log(T) scale
f.ph <- pphsm(f)
## Not run: summary(f.ph) # effects on hazard ratio scale
options(datadist=NULL)
Arguments

**fit.orig**
- object containing the original full-sample fit, with the `x=TRUE` and `y=TRUE` options specified to the model fitting function. This model should be the FULL model including all candidate variables ever excluded because of poor associations with the response.

**fit**
- a function to fit the model, either the original model fit, or a fit in a sample. `fit` has as arguments `x, y, iter, penalty, penalty.matrix, xcol`, and other arguments passed to `predab.resample`. If you don’t want `iter` as an argument inside the definition of `fit`, add ... to the end of its argument list. `iter` is passed to `fit` to inform the function of the sampling repetition number (0=original sample). If `bw=TRUE`, `fit` should allow for the possibility of selecting no predictors, i.e., it should fit an intercept-only model if the model has intercept(s). `fit` must return objects `coef` and `fail` (`fail=TRUE` if `fit` failed due to singularity or non-convergence - these cases are excluded from summary statistics). `fit` must add design attributes to the returned object if `bw=TRUE`. The `penalty.matrix` parameter is not used if `penalty=0`. The `xcol` vector is a vector of columns of `X` to be used in the current model fit. For `ols` and `psm` it includes a 1 for the intercept position. `xcol` is not defined if `iter=0` unless the initial fit had been from a backward step-down. `xcol` is used to select the correct rows and columns of `penalty.matrix` for the current variables selected, for example.

**measure**
- a function to compute a vector of indexes of predictive accuracy for a given fit. For `method=".632"` or `method="crossval"`, it will make the most sense for measure to compute only indexes that are independent of sample size. The measure function should take the following arguments or use `...`: `xbeta` (X beta for current fit), `y`, `evalfit`, `fit`, `iter`, and `fit.orig`. `iter` is as in `fit`. `evalfit` is set to `TRUE` by `predab.resample` if the fit is being evaluated on the sample used to make the fit, `FALSE` otherwise; `fit.orig` is the fit object returned by the original fit on the whole sample. Using `evalfit` will sometimes save computations. For example, in bootstrapping the area under an ROC curve for a logistic regression model, `lrm` already computes the area if the fit is on the training sample. `fit.orig` is used to pass computed configuration parameters from the original fit such as quantiles of predicted probabilities that are used as cut points in other samples. The vector created by `measure` should have `names()` associated with it.

**method**
- The default is "boot" for ordinary bootstrapping (Efron, 1983, Eq. 2.10). Use " .632" for Efron’s .632 method (Efron, 1983, Section 6 and Eq. 6.10), "crossvalidation" for grouped cross-validation, "randomization" for the randomization method. May be abbreviated down to any level, e.g. "b", ".", "cross", "rand".

**bw**
- Set to TRUE to do fast backward step-down for each training sample. Default is FALSE.

**B**
- Number of repetitions, default=50. For `method="crossvalidation"`, this is also the number of groups the original sample is split into.

**pr**
- TRUE to print results for each sample. Default is FALSE.

**prmodsel**
- set to FALSE to suppress printing of model selection output such as that from `fastbw`. 

Stopping rule for fastbw, "aic" or "p". Default is "aic" to use Akaike's information criterion.

Type of statistic to use in stopping rule for fastbw, "residual" (the default) or "individual".

Significance level for stopping in fastbw if rule="p". Default is .05.

Stopping criteria for rule="aic". Stops deleting factors when chi-square - 2 times d.f. falls below aics. Default is 0.

Tolerance for singularity checking. Is passed to fit and fastbw.

Type of statistic to use in stopping rule for fastbw, "residual" (the default) or "individual".

Significance level for stopping in fastbw if rule="p". Default is .05.

Stopping criteria for rule="aic". Stops deleting factors when chi-square - 2 times d.f. falls below aics. Default is 0.

Tolerance for singularity checking. Is passed to fit and fastbw.

For method=".632", the program stops with an error if every observation is not omitted at least once from a bootstrap sample. Efron's " .632" method was developed for measures that are formulated
in terms on per-observation contributions. In general, error measures (e.g., ROC areas) cannot be written in this way, so this function uses a heuristic extension to Efron’s formulation in which it is assumed that the average error measure omitting the 1th observation is the same as the average error measure omitting any other observation. Then weights are derived for each bootstrap repetition and weighted averages over the B repetitions can easily be computed.

**Value**

a matrix of class "validate" with rows corresponding to indexes computed by measure, and the following columns:

- **index.orig**  
  indexes in original overall fit
- **training**  
  average indexes in training samples
- **test**  
  average indexes in test samples
- **optimism**  
  average training-test except for method=".632"-is .632 times (index.orig - test)
- **index.corrected**  
  index.orig-optimism
- **n**  
  number of successful repetitions with the given index non-missing

. Also contains an attribute keepinfo if measure returned such an attribute when run on the original fit.

Predict 

Compute Predicted Values and Confidence Limits

Description

Predict allows the user to easily specify which predictors are to vary. When the vector of values over which a predictor should vary is not specified, the range will be all levels of a categorical predictor or equally-spaced points between the `datadist` "Low:prediction" and "High:prediction" values for the variable (`datadist` by default uses the 10th smallest and 10th largest predictor values in the dataset). Predicted values are the linear predictor (X beta), a user-specified transformation of that scale, or estimated probability of surviving past a fixed single time point given the linear predictor. Predict is usually used for plotting predicted values but there is also a print method.

When the first argument to `Predict` is a fit object created by `bootcov` with `coef.reps=TRUE`, confidence limits come from the stored matrix of bootstrap repetitions of coefficients, using bootstrap percentile nonparametric confidence limits, basic bootstrap, or BCa limits. Such confidence intervals do not make distributional assumptions. You can force `Predict` to instead use the bootstrap covariance matrix by setting `usebootcoef=FALSE`. If `coef.reps` was `FALSE`, `usebootcoef=FALSE` is the default.

There are `ggplot`, `plotp`, and `plot` methods for `Predict` objects that makes it easy to show predicted values and confidence bands.

The `rbind` method for `Predict` objects allows you to create separate sets of predictions under different situations and to combine them into one set for feeding to `plot.Predict`, `ggplot.Predict`, or `plotp.Predict`. For example you might want to plot confidence intervals for means and for individuals using ols, and have the two types of confidence bands be superposed onto one plot or placed into two panels. Another use for `rbind` is to combine predictions from quantile regression models that predicted three different quantiles.

If `conf.type="simultaneous"`, simultaneous (over all requested predictions) confidence limits are computed. See the `predictrms` function for details.

If `fun` is given, `conf.int > 0`, the model is not a Bayesian model, and the bootstrap was not used, `fun` may return limits attribute when `fun` computed its own confidence limits. These confidence limits will be functions of the design matrix, not just the linear predictor.

Usage

```r
Predict(object, ..., fun=NULL, funint=TRUE, 
type = c("predictions", "model.frame", "x"), 
np = 200, conf.int = 0.95, 
conf.type = c("mean", "individual","simultaneous"), 
usebootcoef=TRUE, boot.type=c("percentile", "bca", "basic"), 
posterior.summary=c('mean', 'median', 'mode'), 
adj.zero = FALSE, ref.zero = FALSE, 
kint=NULL, ycut=NULL, time = NULL, loglog = FALSE, digits=4, name, 
factors=NULL, offset=NULL)
```

## S3 method for class 'Predict'

```r
```
Predict

\[ \text{print}(x,...) \]

## S3 method for class 'Predict'
\[ \text{rbind}(..., \text{name}) \]

**Arguments**

- **object**: an `rms` fit object, or for print the result of `Predict`. `options(datadist="d")` must have been specified (where `d` was created by `datadist`), or it must have been in effect when the the model was fitted.

- **...**: One or more variables to vary, or single-valued adjustment values. Specify a variable name without an equal sign to use the default display range, or any range you choose (e.g. `seq(0,100,by=2),c(2,3,7,14)`). The default list of values for which predictions are made is taken as the list of unique values of the variable if they number fewer than 11. For variables with \( > 10 \) unique values, `np` equally spaced values in the range are used for plotting if the range is not specified. Variables not specified are set to the default adjustment value limits[2], i.e. the median for continuous variables and a reference category for non-continuous ones. Later variables define adjustment settings. For categorical variables, specify the class labels in quotes when specifying variable values. If the levels of a categorical variable are numeric, you may omit the quotes. For variables not described using `datadist`, you must specify explicit ranges and adjustment settings for predictors that were in the model. If no variables are specified in ..., predictions will be made by separately varying all predictors in the model over their default range, holding the other predictors at their adjustment values. This has the same effect as specifying `name` as a vector containing all the predictors. For `rbind`, ... represents a series of results from `Predict`. If you name the results, these names will be taken as the values of the new .set. variable added to the concatenated data frames. See an example below.

- **fun**: an optional transformation of the linear predictor. Specify `fun='mean'` if the fit is a proportional odds model fit and you ran `bootcov` with `coef.reps=TRUE`. This will let the mean function be re-estimated for each bootstrap rep to properly account for all sources of uncertainty in estimating the mean response. `fun` can be a general function and can compute confidence limits (stored as a list in the `limits` attribute) of the transformed parameters such as means.

- **funint**: set to `FALSE` if `fun` is not a function such as the result of `Mean`, `Quantile`, or `ExProb` that contains an intercepts argument

- **type**: defaults to providing predictions. Set to "model.frame" to return a data frame of predictor settings used. Set to "x" to return the corresponding design matrix constructed from the predictor settings.

- **np**: the number of equally-spaced points computed for continuous predictors that vary, i.e., when the specified value is . or `NA`

- **conf.int**: confidence level (highest posterior density interval probability for Bayesian models). Default is 0.95. Specify `FALSE` to suppress.

- **conf.type**: type of confidence interval. Default is "mean" which applies to all models. For models containing a residual variance (e.g. ols), you can specify `conf.type="individual"
instead, to obtain limits on the predicted value for an individual subject. Specify conf.type="simultaneous" to obtain simultaneous confidence bands for mean predictions with family-wise coverage of conf.int.

usebootcoef set to FALSE to force the use of the bootstrap covariance matrix estimator even when bootstrap coefficient reps are present

boot.type set to 'bca' to compute BCa confidence limits or 'basic' to use the basic bootstrap. The default is to compute percentile intervals

posterior.summary defaults to using the posterior mean of the regression coefficients. Specify 'mode' or 'median' to instead use the other summaries.

adj.zero Set to TRUE to adjust all non-plotted variables to 0 (or reference cell for categorical variables) and to omit intercept(s) from consideration. Default is FALSE.

ref.zero Set to TRUE to subtract a constant from $X\beta$ before plotting so that the reference value of the x-variable yields $y=0$. This is done before applying function fun. This is especially useful for Cox models to make the hazard ratio be 1.0 at reference values, and the confidence interval have width zero.

kint This is only useful in a multiple intercept model such as the ordinal logistic model. There to use to second of three intercepts, for example, specify kint=2. The default is 1 for lrm and the middle intercept corresponding to the median $y$ for orm or blrm. You can specify ycutoff instead, and the intercept corresponding to $Y \geq ycutoff$ will be used for kint.

ycut for an ordinal model specifies the Y cutoff to use in evaluating departures from proportional odds, when the constrained partial proportional odds model is used. When omitted, ycutoff is implied by kint. The only time it is absolutely mandatory to specify ycutoff is when computed an effect (e.g., odds ratio) at a level of the response variable that did not occur in the data. This would only occur when the cppo function given to blrm is a continuous function.

time Specify a single time $u$ to cause function survest to be invoked to plot the probability of surviving until time $u$ when the fit is from cph or psm.

loglog Specify loglog=TRUE to plot log[-log(survival)] instead of survival, when time is given.

digits Controls how “adjust-to” values are plotted. The default is 4 significant digits.

name Instead of specifying the variables to vary in the variables (...) list, you can specify one or more variables by specifying a vector of character string variable names in the name argument. Using this mode you cannot specify a list of variable values to use; prediction is done as if you had said e.g. age without the equal sign. Also, interacting factors can only be set to their reference values using this notation.

factors an alternate way of specifying ..., mainly for use by survplot or gendata. This must be a list with one or more values for each variable listed, with NA values for default ranges.

offset a list containing one value for one variable, which is mandatory if the model included an offset term. The variable name must match the innermost variable name in the offset term. The single offset is added to all predicted values.
x  an object created by Predict
rename  If you are concatenating predictor sets using rbind and one or more of the variables were renamed for one or more of the sets, but these new names represent different versions of the same predictors (e.g., using or not using imputation), you can specify a named character vector to rename predictors to a central name. For example, specify rename=c(age.imputed='age', corrected.bp='bp') to rename from old names age.imputed, corrected.bp to age, bp. This happens before concatenation of rows.

Details

When there are no intercepts in the fitted model, plot subtracts adjustment values from each factor while computing variances for confidence limits.

Specifying time will not work for Cox models with time-dependent covariables. Use survest or survfit for that purpose.

Value

a data frame containing all model predictors and the computed values yhat, lower, upper, the latter two if confidence intervals were requested. The data frame has an additional class "Predict". If name is specified or no predictors are specified in ..., the resulting data frame has an additional variable called .predictor. specifying which predictor is currently being varied. .predictor. is handy for use as a paneling variable in lattice or ggplot2 graphics.

Predict(g, offset=list(N=100))

## End(Not run)
options(datadist=NULL)
**Description**

Computes a variety of types of predicted values for fits from `lrm` and `orm`, either from the original dataset or for new observations. The `Mean.lrm` and `Mean.orm` functions produce an R function to compute the predicted mean of a numeric ordered response variable given the linear predictor, which is assumed to use the first intercept when it was computed. The returned function has two optional arguments if confidence intervals are desired: `conf.int` and the design matrix `X`. When this derived function is called with nonzero `conf.int`, an attribute named `limits` is attached to the estimated mean. This is a list with elements lower and upper containing normal approximations for confidence limits using the delta method.

**Usage**

```r
## S3 method for class 'lrm'
predict(object, ..., type=c("lp", "fitted", "fitted.ind", "mean", "x", "data.frame", "terms", "cterms", "ccterms", "adjto","adjto.data.frame", "model.frame"), se.fit=FALSE, codes=FALSE)
## S3 method for class 'orm'
predict(object, ..., type=c("lp", "fitted", "fitted.ind", "mean", "x", "data.frame", "terms", "cterms", "ccterms", "adjto","adjto.data.frame", "model.frame"), se.fit=FALSE, codes=FALSE)

## S3 method for class 'lrm'
Mean(object, codes=FALSE, ...)
## S3 method for class 'orm'
Mean(object, codes=FALSE, ...)
```

**Arguments**

- **object**
  - a object created by `lrm` or `orm`

- **...**
  - arguments passed to `predictrms`, such as `kint` and `newdata` (which is used if you are predicting out of data). See `predictrms` to see how NAs are handled. Ignored for other functions.

- **type**
  - See `predict.rms` for "x", "data.frame", "terms", "cterms", "ccterms", "adjto", "adjto.data.frame" and "model.frame". `type="lp"` is used to get linear predictors (using the first intercept by default; specify `kint` to use others). `type="fitted"` is used to get all the probabilities \( Y \geq j \). `type="fitted.ind"` gets all the individual probabilities \( Y = j \) (not recommended for `orm` fits). For an ordinal response variable, `type="mean"` computes the estimated mean \( Y \) by summing values of \( Y \) multiplied by the estimated \( \text{Prob}(Y = j) \). If \( Y \) was a character or factor object, the levels are the character values or factor levels, so these must be translatable to numeric, unless `codes=TRUE`. See the Hannah and Quigley reference below for the method of estimating (and presenting) the mean score. If you specify `type="fitted","fitted.ind","mean"` you may not specify `kint`.

- **se.fit**
  - applies only to `type="lp"`, to get standard errors.
codes if TRUE, type="mean", Mean.lrm, and Mean.orm use the integer codes 1, 2, ..., k for the k-level response in computing the predicted mean response.

Value

a vector (type="lp" with se.fit=FALSE, or type="mean" or only one observation being predicted), a list (with elements linear.predictors and se.fit if se.fit=TRUE), a matrix (type="fitted" or type="fitted.ind"), a data frame, or a design matrix. For Mean.lrm and Mean.orm, the result is an R function.

## predictrms

### Predicted Values from Model Fit

**Description**

The `predict` function is used to obtain a variety of values or predicted values from either the data
used to fit the model (if `type="adjto"` or `adjto.data.frame` or if `x=TRUE` or `linear.predictors=TRUE`
were specified to the modeling function), or from a new dataset. Parameters such as knots and factor
levels used in creating the design matrix in the original fit are "remembered". See the `Function`
function for another method for computing the linear predictors. `predictrms` is an internal utility
function that is for the other functions.

**Usage**

```r
predictrms(fit, newdata=NULL,
  type=c("lp", "x", "data.frame", "terms", "cterms", "ccterms",
  "adjto", "adjto.data.frame", "model.frame"),
  se.fit=FALSE, conf.int=FALSE,
  conf.type=c("mean", "individual", "simultaneous"),
  kint=NULL, na.action=na.keep, expand.na=TRUE,
  center.terms=type=="terms", ref.zero=FALSE,
  posterior.summary=c("mean", "median", "mode"),
  second=FALSE, ...)
## S3 method for class 'bj'
predict(object, newdata,
  type=c("lp", "x", "data.frame", "terms", "cterms", "ccterms",
  "adjto", "adjto.data.frame", "model.frame"),
  se.fit=FALSE, conf.int=FALSE,
  conf.type=c("mean","individual","simultaneous"),
  kint=1,
  na.action=na.keep, expand.na=TRUE,
  center.terms=type=="terms", ...) # for bj

## S3 method for class 'cph'
predict(object, newdata=NULL,
  type=c("lp", "x", "data.frame", "terms", "cterms", "ccterms",
  "adjto", "adjto.data.frame", "model.frame"),
  se.fit=FALSE, conf.int=FALSE,
```
Arguments

object, fit  a fit object with an `rms` fitting function

newdata  An S data frame, list or a matrix specifying new data for which predictions are desired. If `newdata` is a list, it is converted to a matrix first. A matrix is converted to a data frame. For the matrix form, categorical variables (`catg` or `strat`) must be coded as integer category numbers corresponding to the order in which value labels were stored. For list or matrix forms, matrix factors must be
given a single value. If this single value is the missing value NA, the adjustment values of matrix (the column medians) will later replace this value. If the single value is not NA, it is propagated throughout the columns of the matrix factor. For factor variables having numeric levels, you can specify the numeric values in newdata without first converting the variables to factors. These numeric values are checked to make sure they match a level, then the variable is converted internally to a factor. It is most typical to use a data frame for newdata, and the S function expand.grid is very handy here. For example, one may specify newdata=expand.grid(age=c(10,20,30), race=c("black","white","other"), chol=seq(100,300,by=25)).

type
Type of output desired. The default is "lp" to get the linear predictors - predicted $X\beta$. For Cox models, these predictions are centered. You may specify "x" to get an expanded design matrix at the desired combinations of values, "data.frame" to get an S data frame of the combinations, "model.frame" to get a data frame of the transformed predictors, "terms" to get a matrix with each column being the linear combination of variables making up a factor (with separate terms for interactions), "cterms" ("combined terms") to not create separate terms for interactions but to add all interaction terms involving each predictor to the main terms for each predictor, "cterms" to combine all related terms (related through interactions) and their interactions into a single column, "adjto" to return a vector of limits[2] (see datadist) in coded form, and "adjto.data.frame" to return a data frame version of these central adjustment values. Use of type="cterms" does not make sense for a strat variable that does not interact with another variable. If newdata is not given, predict will attempt to return information stored with the fit object if the appropriate options were used with the modeling function (e.g., x, y, linear.predictors, se.fit).

se.fit
Defaults to FALSE. If type="linear.predictors", set se.fit=TRUE to return a list with components linear.predictors and se.fit instead of just a vector of fitted values. For Cox model fits, standard errors of linear predictors are computed after subtracting the original column means from the new design matrix.

conf.int
Specify conf.int as a positive fraction to obtain upper and lower confidence intervals (e.g., conf.int=0.95). The $t$-distribution is used in the calculation for ols fits. Otherwise, the normal critical value is used. For Bayesian models conf.int is the highest posterior density interval probability.

conf.type
specifies the type of confidence interval. Default is for the mean. For ols fits there is the option of obtaining confidence limits for individual predicted values by specifying conf.type="individual".

posterior.summary
when making predictions from a Bayesian model, specifies whether you want the linear predictor to be computed from the posterior mean of parameters (default) or the posterior mode or median median

second
set to TRUE to use the model’s second formula. At present this pertains only to a partial proportional odds model fitted using the blrm function. When second=TRUE and type='x' the Z design matrix is returned (that goes with the
tau parameters in the partial PO model). When type='lp' is specified Z*tau is computed. In neither case is the result is multiplied by the by the cppo function.

**kint**

A single integer specifying the number of the intercept to use in multiple-intercept models. The default is 1 for lrm and the reference median intercept for orm and blrm. For a partial PO model, kint should correspond to the response variable value that will be used when dealing with second=TRUE.

**na.action**

Function to handle missing values in newdata. For predictions "in data", the same na.action function that was used during model fitting is used to define an naresid function to possibly restore rows of the data matrix that were deleted due to NAs. For predictions "out of data", the default na.action is na.keep, resulting in NA predictions when a row of newdata has an NA. Whatever na.action is in effect at the time for "out of data" predictions, the corresponding naresid is used also.

**expand.na**

Set to FALSE to keep the naresid from having any effect, i.e., to keep from adding back observations removed because of NAs in the returned object. If expand.na=FALSE, the na.action attribute will be added to the returned object.

**center.terms**

Set to FALSE to suppress subtracting adjust-to values from columns of the design matrix before computing terms with type="terms".

**ref.zero**

Set to TRUE to subtract a constant from Xβ before plotting so that the reference value of the x-variable yields y=0. This is done before applying function fun. This is especially useful for Cox models to make the hazard ratio be 1.0 at reference values, and the confidence interval have width zero.

**Details**

datadist and options(datadist=) should be run before predictrms if using type="adjto", type="adjto.data.frame", or type="terms", or if the fit is a Cox model fit and you are requesting se.fit=TRUE. For these cases, the adjustment values are needed (either for the returned result or for the correct covariance matrix computation).

print.cph

Print cph Results

Description

Formatted printing of an object of class cph. Prints strata frequencies, parameter estimates, standard errors, z-statistics, numbers of missing values, etc. Format of output is controlled by the user previously running `options(prType="lang")` where lang is "plain" (the default), "latex", or "html".
Usage

```r
## S3 method for class 'cph'
print(x, digits=4, r2=c(0,2,4), table=TRUE, conf.int=FALSE, coefs=TRUE, pg=FALSE, title="Cox Proportional Hazards Model", ...)
```

Arguments

- `x` fit object
- `digits` number of digits to right of decimal place to print
- `r2` vector of integers specifying which $R^2$ measures to print, with 0 for Nagelkerke $R^2$ and 1:4 corresponding to the 4 measures computed by `R2Measures`. Default is to print Nagelkerke (labeled $R^2$) and second and fourth `R2Measures` which are the measures adjusted for the number of predictors, first for the raw sample size then for the effective sample size, which here is the number of non-censored observations.
- `conf.int` set to e.g. .95 to print 0.95 confidence intervals on simple hazard ratios (which are usually meaningless as one-unit changes are seldom relevant and most models contain multiple terms per predictor)
- `table` set to `FALSE` to suppress event frequency statistics
- `coefs` specify `coefs=FALSE` to suppress printing the table of model coefficients, standard errors, etc. Specify `coefs=n` to print only the first n regression coefficients in the model.
- `pg` set to `TRUE` to print g-indexes
- `title` a character string title to be passed to `prModFit`
- `...` arguments passed to `prModFit`

See Also

`coxph, prModFit`

Description

Print a ‘Glm’ Object

Usage

```r
## S3 method for class 'Glm'
print(x, digits = 4, coefs = TRUE, title = "General Linear Model", ...)
```
Arguments

x  'Glm' object
digits  number of significant digits to print
coefs  specify 'coefs=FALSE' to suppress printing the table of
title  a character string title to be passed to 'prModFit'
...  ignored

Details

Prints a 'Glm' object, optionally in LaTeX or html

Author(s)

Frank Harrell

---

print.impactPO  Print Result from impactPO

Description

Prints statistical summaries and optionally predicted values computed by impactPO, transposing statistical summaries for easy reading

Usage

## S3 method for class 'impactPO'
print(x, estimates = nrow(x$estimates) < 16, ...)

Arguments

x  an object created by impactPO
estimates  set to FALSE to suppress printing estimated category probabilities. Defaults to TRUE when the number of rows < 16.
...  ignored

Author(s)

Frank Harrell
Description

Formatted printing of an object of class `ols` using methods taken from `print.lm` and `summary.lm`. Prints R-squared, adjusted R-squared, parameter estimates, standard errors, and t-statistics (Z statistics if penalized estimation was used). For penalized estimation, prints the maximum penalized likelihood estimate of the residual standard deviation (Sigma) instead of the usual root mean squared error. Format of output is controlled by the user previously running `options(prType="lang")` where lang is "plain" (the default), "latex", or "html".

Usage

```r
## S3 method for class 'ols'
print(x, digits=4, long=FALSE, coefs=TRUE,
     title="Linear Regression Model", ...)
```

Arguments

- `x` : fit object
- `digits` : number of significant digits to print
- `long` : set to `TRUE` to print the correlation matrix of parameter estimates
- `coefs` : specify `coefs=FALSE` to suppress printing the table of model coefficients, standard errors, etc. Specify `coefs=n` to print only the first `n` regression coefficients in the model.
- `title` : a character string title to be passed to `prModFit`
- `...` : other parameters to pass to `print` or `format`

Description

`psm` is a modification of Therneau’s `survreg` function for fitting the accelerated failure time family of parametric survival models. `psm` uses the `rms` class for automatic anova, fastbw, calibrate, validate, and other functions. `Hazard.psm`, `Survival.psm`, `Quantile.psm`, and `Mean.psm` create S functions that evaluate the hazard, survival, quantile, and mean (expected value) functions analytically, as functions of time or probabilities and the linear predictor values. The Nagelkerke $R^2$ and and adjusted Maddala-Cox-Snell $R^2$ are computed. For the latter the notation is $R^2(p,m)$
where p is the number of regression coefficients being adjusted for and m is the effective sample size (number of uncensored observations). See R2Measures for more information.

For the print method, format of output is controlled by the user previously running options(prType="lang") where lang is "plain" (the default), "latex", or "html".

The residuals.psm function exists mainly to compute normalized (standardized) residuals and to censor them (i.e., return them as Surv objects) just as the original failure time variable was censored. These residuals are useful for checking the underlying distributional assumption (see the examples). To get these residuals, the fit must have specified y=TRUE. A lines method for these residuals automatically draws a curve with the assumed standardized survival distribution. A survplot method runs the standardized censored residuals through npsurv to get Kaplan-Meier estimates, with optional stratification (automatically grouping a continuous variable into quantiles) and then through survplot.npsurv to plot them. Then lines is invoked to show the theoretical curve. Other types of residuals are computed by residuals using residuals.survreg.

Usage

psm(formula,
     data=environment(formula), weights,
     subset, na.action=na.delete, dist="weibull",
     init=NULL, scale=0,
     control=survreg.control(),
     parms=NULL,
     model=FALSE, x=FALSE, y=TRUE, time.inc, ...)

## S3 method for class 'psm'
print(x, correlation=FALSE, digits=4, r2=c(0,2,4), coefs=TRUE,
      pg=FALSE, title, ...)

Hazard(object, ...)
## S3 method for class 'psm'
Hazard(object, ...)  # for psm fit
  # E.g. lambda <- Hazard(fit)

Survival(object, ...)
## S3 method for class 'psm'
Survival(object, ...)  # for psm
  # E.g. survival <- Survival(fit)

## S3 method for class 'psm'
Quantile(object, ...), # for psm
  # E.g. quantsurv <- Quantile(fit)

## S3 method for class 'psm'
Mean(object, ...)  # for psm
  # E.g. meant <- Mean(fit)

# lambda(times, lp)  # get hazard function at t=times, xbeta=lp
# survival(times, lp) # survival function at t=times, lp
# quantile_surv(q, lp)  # quantiles of survival time
# mean_surv(lp)        # mean survival time

## S3 method for class 'psm'
residuals(object, type=c("censored.normalized", "response", "deviance", "dfbeta", "dfbetas", "working", "ldcase", "ldresp", "ldshape", "matrix", "score"), ...)

## S3 method for class 'residuals.psm.censored.normalized'
survplot(fit, x, g=4, col, main, ...)

## S3 method for class 'residuals.psm.censored.normalized'
lines(x, n=100, lty=1, xlim, lwd=3, ...)

# for type="censored.normalized"

**Arguments**

- **formula**: an S statistical model formula. Interactions up to third order are supported. The left hand side must be a `Surv` object.
- **object**: a fit created by `psm`. For `survplot` with residuals from `psm`, `object` is the result of `residuals.psm`.
- **fit**: a fit created by `psm`.
- **data, subset, weights, dist, scale, init, na.action, control**
  - see `survreg`.
- **parms**: a list of fixed parameters. For the t-distribution this is the degrees of freedom; most of the distributions have no parameters.
- **model**: set to TRUE to include the model frame in the returned object.
- **x**: set to TRUE to include the design matrix in the object produced by `psm`. For the `survplot` method, `x` is an optional stratification variable (character, numeric, or categorical). For `lines.residuals.psm.censored.normalized`, `x` is the result of `residuals.psm`. For `print` it is the result of `psm`.
- **y**: set to TRUE to include the `Surv()` matrix.
- **time.inc**: setting for default time spacing. Used in constructing time axis in `survplot`, and also in make confidence bars. Default is 30 if time variable has units="Day", 1 otherwise, unless maximum follow-up time < 1. Then max time/10 is used as time.inc. If time.inc is not given and max time/default time.inc is > 25, time.inc is increased.
- **correlation**: set to TRUE to print the correlation matrix for parameter estimates.
- **digits**: number of places to print to the right of the decimal point.
- **r2**: vector of integers specifying which R^2 measures to print, with 0 for Nagelkerke R^2 and 1:4 corresponding to the 4 measures computed by `R2Measures`. Default is to print Nagelkerke (labeled R2) and second and fourth `R2Measures` which are the measures adjusted for the number of predictors, first for the raw sample size then for the effective sample size, which here is the number of uncensored observations.
coefs specify coefs=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.

pg set to TRUE to print g-indexes

title a character string title to be passed to prModFit

... other arguments to fitting routines, or to pass to survplot from survplot.residuals.psm.censored.normalized. Passed to the generic lines function for lines.

times a scalar or vector of times for which to evaluate survival probability or hazard

lp a scalar or vector of linear predictor values at which to evaluate survival probability or hazard. If both times and lp are vectors, they must be of the same length.

q a scalar or vector of probabilities. The default is .5, so just the median survival time is returned. If q and lp are both vectors, a matrix of quantiles is returned, with rows corresponding to lp and columns to q.

type type of residual desired. Default is censored normalized residuals, defined as (link(Y) - linear.predictors)/scale parameter, where the link function was usually the log function. See survreg for other types. type="score" returns the score residual matrix.

n number of points to evaluate theoretical standardized survival function for lines.residuals.psm.censored.normalized

lty line type for lines, default is 1

xlim range of times (or transformed times) for which to evaluate the standardized survival function. Default is range in normalized residuals.

lwd line width for theoretical distribution, default is 3

g number of quantile groups to use for stratifying continuous variables having more than 5 levels

col vector of colors for survplot method, corresponding to levels of x (must be a scalar if there is no x)

main main plot title for survplot. If omitted, is the name or label of x if x is given. Use main="" to suppress a title when you specify x.

Details

The object survreg.distributions contains definitions of properties of the various survival distributions.

psm does not trap singularity errors due to the way survreg.fit does matrix inversion. It will trap non-convergence (thus returning fit$fail=TRUE) if you give the argument failure=2 inside the control list which is passed to survreg.fit. For example, use f <- psm(S ~ x, control=list(failure=2, maxiter=20)) to allow up to 20 iterations and to set f$fail=TRUE in case of non-convergence. This is especially useful in simulation work.
Value

`psm` returns a fit object with all the information `survreg` would store as well as what `rms` stores and units and `time.inc`. `Hazard`, `Survival`, and `Quantile` return S-functions. `residuals.psm` with `type="censored.normalized"` returns a `Surv` object which has a special attribute "theoretical" which is used by the `lines` routine. This is the assumed standardized survival function as a function of time or transformed time.

options(datadist=NULL)

residuals.cph  Residuals for a cph Fit

Description

Calculates martingale, deviance, score or Schoenfeld residuals (scaled or unscaled) or influence statistics for a Cox proportional hazards model. This is a slightly modified version of Therneau's residuals.coxph function. It assumes that x=TRUE and y=TRUE were specified to cph, except for martingale residuals, which are stored with the fit by default.
Usage

## S3 method for class 'cph'
residuals(object,
    type=c("martingale", "deviance", "score", "schoenfeld", "dfbeta", "dfbetas", "scaledsch", "partial"), ...)

Arguments

object
    a cph object
type
    character string indicating the type of residual desired; the default is martingale. Only enough of the string to determine a unique match is required. Instead of the usual residuals, type="dfbeta" may be specified to obtain approximate leave-out-one ∆βs. Use type="dfbetas" to normalize the ∆βs for the standard errors of the regression coefficient estimates. Scaled Schoenfeld residuals (type="scaledsch", Grambsch and Therneau, 1993) better reflect the log hazard ratio function than ordinary Schoenfeld residuals, and they are on the regression coefficient scale. The weights use Grambsch and Therneau's "average variance" method.

... see residuals.coxph

Value

The object returned will be a vector for martingale and deviance residuals and matrices for score and schoenfeld residuals, dfbeta, or dfbetas. There will be one row of residuals for each row in the input data (without collapse). One column of score and Schoenfeld residuals will be returned for each column in the model.matrix. The scaled Schoenfeld residuals are used in the cox.zph function.

The score residuals are each individual’s contribution to the score vector. Two transformations of this are often more useful: dfbeta is the approximate change in the coefficient vector if that observation were dropped, and dfbetas is the approximate change in the coefficients, scaled by the standard error for the coefficients.

par(mfrow=c(1,1))

---

residuals.lrm  Residuals from an lrm or orm Fit
Description

For a binary logistic model fit, computes the following residuals, letting \( P \) denote the predicted probability of the higher category of \( Y \), \( X \) denote the design matrix (with a column of 1s for the intercept), and \( L \) denote the logit or linear predictors: ordinary or Li-Shepherd \((Y - P)\), score \( (X(Y-P))/\sqrt{P(1-P)} \), deviance \( (\log(1-P)) \), pseudo dependent variable used in influence statistics \( (L + (Y-P)/(P(1-P))) \), and partial \( (X_i\beta_i + (Y-P)/(P(1-P))) \).

Will compute all these residuals for an ordinal logistic model, using as temporary binary responses dichotomizations of \( Y \), along with the corresponding \( P \), the probability that \( Y \geq \) cutoff. For type="partial", all possible dichotomizations are used, and for type="score", the actual components of the first derivative of the log likelihood are used for an ordinal model. For type="li.shepherd" the residual is \( Pr(W < Y) - Pr(W > Y) \) where \( Y \) is the observed response and \( W \) is a random variable from the fitted distribution. Alternatively, specify type="score.binary" to use binary model score residuals but for all cutpoints of \( Y \) (plotted only, not returned). The score.binary, partial, and perhaps score residuals are useful for checking the proportional odds assumption. If the option pl=TRUE is used to plot the score or score.binary residuals, a score residual plot is made for each column of the design (predictor) matrix, with \( Y \) cutoffs on the x-axis and the mean +/- 1.96 standard errors of the score residuals on the y-axis. You can instead use a box plot to display these residuals, for both score.binary and score. Proportional odds dictates a horizontal score.binary plot. Partial residual plots use smooth nonparametric estimates, separately for each cutoff of \( Y \). One examines that plot for parallelism of the curves to check the proportional odds assumption, as well as to see if the predictor behaves linearly.

Also computes a variety of influence statistics and the le Cessie - van Houwelingen - Copas - Hosmer unweighted sum of squares test for global goodness of fit, done separately for each cutoff of \( Y \) in the case of an ordinal model.

The plot.lrm.partial function computes partial residuals for a series of binary logistic model fits that all used the same predictors and that specified x=TRUE, y=TRUE. It then computes smoothed partial residual relationships (using lowess with iter=0) and plots them separately for each predictor, with residual plots from all model fits shown on the same plot for that predictor.

Usage

```r
## S3 method for class 'lrm'
residuals(object, type=c("li.shepherd","ordinary","score","score.binary","pearson","deviance","pseudo.dep","partial","dfbeta","dfbetas","dffit","dffits","hat","gof","lp1"),
          pl=FALSE, xlim, ylim, kint, label.curves=TRUE, which, ...)
## S3 method for class 'orm'
residuals(object, type=c("li.shepherd","ordinary","score","score.binary","pearson","deviance","pseudo.dep","partial","dfbeta","dfbetas","dffit","dffits","hat","gof","lp1"),
          pl=FALSE, xlim, ylim, kint, label.curves=TRUE, which, ...)
## S3 method for class 'lrm.partial'
plot(..., labels, center=FALSE, ylim)
```
residuals.lrm

Arguments

object

object created by lrm or orm

... for residuals, applies to type="partial" when pl is not FALSE. These are extra arguments passed to the smoothing function. Can also be used to pass extra arguments to boxplot for type="score" or "score.binary". For plot.lrm.partial this specifies a series of binary model fit objects.

type
type of residual desired. Use type="lp1" to get approximate leave-out-1 linear predictors, derived by subtracting the dffit from the original linear predictor values.

pl

applies only to type="partial", "score", and "score.binary". For score residuals in an ordinal model, set pl=TRUE to get means and approximate 0.95 confidence bars vs. Y, separately for each X. Alternatively, specify pl="boxplot" to use boxplot to draw the plot, with notches and with width proportional to the square root of the cell sizes. For partial residuals, set pl=TRUE (which uses lowess) or pl="supsmu" to get smoothed partial residual plots for all columns of X using supsmu. Use pl="loess" to use loess and get confidence bands ("loess" is not implemented for ordinal responses). Under R, pl="loess" uses lowess and does not provide confidence bands. If there is more than one X, you should probably use par(mfrow=c( , )) before calling resid. Note that pl="loess" results in plot.loess being called, which requires a large memory allocation.

xlim

plotting range for x-axis (default = whole range of predictor)

ylim

plotting range for y-axis (default = whole range of residuals, range of all confidence intervals for score or score.binary or range of all smoothed curves for partial if pl=TRUE, or 0.1 and 0.9 quantiles of the residuals for pl="boxplot").

kint

for an ordinal model for residuals other than li.shepherd, partial, score, or score.binary, specifies the intercept (and the cutoff of Y) to use for the calculations. Specifying kint=2, for example, means to use Y ≥ 3rd level.

label.curves

set to FALSE to suppress curve labels when type="partial". The default, TRUE, causes labcurve to be invoked to label curves where they are most separated. label.curves can be a list containing the opts parameter for labcurve, to send options to labcurve, such as tilt. The default for tilt here is TRUE.

which

a vector of integers specifying column numbers of the design matrix for which to compute or plot residuals, for type="partial", "score", "score.binary".

labels

for plot.lrm.partial this specifies a vector of character strings providing labels for the list of binary fits. By default, the names of the fit objects are used as labels. The labcurve function is used to label the curve with the labels.

center

for plot.lrm.partial this causes partial residuals for every model to have a mean of zero before smoothing and plotting

Details

For the goodness-of-fit test, the le Cessie-van Houwelingen normal test statistic for the unweighted sum of squared errors (Brier score times n) is used. For an ordinal response variable, the test for predicting the probability that Y ≥ j is done separately for all j (except the first). Note that the test statistic can have strange behavior (i.e., it is far too large) if the model has no predictive value.
For most of the values of type, you must have specified x=TRUE, y=TRUE to lrm or orm.

There is yet no literature on interpreting score residual plots for the ordinal model. Simulations when proportional odds is satisfied have still shown a U-shaped residual plot. The series of binary model score residuals for all cutoffs of Y seems to better check the assumptions. See the examples.

The li.shepherd residual is a single value per observation on the probability scale and can be useful for examining linearity, checking for outliers, and measuring residual correlation.

**Value**

a matrix (type="partial","dfbeta","dfbetas","score"), test statistic (type="gof"), or a vector otherwise. For partial residuals from an ordinal model, the returned object is a 3-way array (rows of X by columns of X by cutoffs of Y), and NAs deleted during the fit are not re-inserted into the residuals. For score.binary, nothing is returned.

### residuals.ols

**Residuals for ols**

**Description**

Computes various residuals and measures of influence for a fit from ols.

**Usage**

```r
## S3 method for class 'ols'
residuals(object,
         type=c("ordinary", "score", "dfbeta", "dfbetas",
                "dffit", "dffits", "hat", "hscore", "influence.measures"), ...)
```

**Arguments**

- `object`: object created by ols. Depending on `type`, you may have had to specify `x=TRUE` to ols.
type

type of residual desired. "ordinary" refers to the usual residual. "score" is the matrix of score residuals (contributions to first derivative of log likelihood). dfbeta and dfbetas mean respectively the raw and normalized matrix of changes in regression coefficients after deleting in turn each observation. The coefficients are normalized by their standard errors. hat contains the leverages — diagonals of the “hat” matrix. dffit and dffits contain respectively the difference and normalized difference in predicted values when each observation is omitted. The S lm.influence function is used. When type="hscore", the ordinary residuals are divided by one minus the corresponding hat matrix diagonal element to make residuals have equal variance. When type="influence.measures" the model is converted to an lm model and influence.measures(object)$infmat is returned. This is a matrix with dfbetas for all predictors, dffit, cov.r, Cook's d, and hat. See the help file for influence.measures for more details.

Value

a matrix or vector, with places for observations that were originally deleted by ols held by NAs

Examples

set.seed(1)
x1 <- rnorm(100)x2 <- rnorm(100)x1[1] <- 100y <- x1 + x2 + rnorm(100)f <- ols(y ~ x1 + x2, x=TRUE, y=TRUE)
resid(f, "dfbetas")which.influence(f)i <- resid(f, 'influence.measures') # dfbeta, dffit, etc.
**Description**

This is a series of special transformation functions (asis, pol, lsp, rcs, catg, scored, strat, matrx), fitting functions (e.g., lrm, cph, psm, or ols), and generic analysis functions (anova.rms, summary.rms, Predict, plot.Predict, ggplot.Predict, survplot, fastbw, validate, calibrate, specs.rms, which.influence, latexrms, nomogram, datadist, gendata) that help automate many analysis steps, e.g., fitting restricted interactions and multiple stratification variables, analysis of variance (with tests of linearity of each factor and pooled tests), plotting effects of variables in the model, estimating and graphing effects of variables that appear non-linearly in the model using e.g. inter-quartile-range hazard ratios, bootstrapping model fits, and constructing nomograms for obtaining predictions manually. Behind the scene is the Design function which stores extra attributes. Design() is not intended to be called by users. Design causes detailed design attributes and descriptions of the distribution of predictors to be stored in an attribute of the terms component called Design.

modelData is a replacement for model.frame.default that is much streamlined and prepares data for Design(). If a second formula is present, modelData ensures that missing data deletions are the same for both formulas, and produces a second model frame for formula2 as the data2 attribute of the main returned data frame.

**Usage**

```r
modelData(data=environment(formula), formula, formula2=NULL, weights, subset, na.action=na.delete, dotexpand=TRUE, callenv=parent.frame(n=2))

Design(mf, formula=NULL, specials=NULL, allow.offset=TRUE, intercept=1)
# not to be called by the user; called by fitting routines
# dist <- datadist(x1,x2,sex,age,race,bp)
# or dist <- datadist(my.data.frame)
# Can omit call to datadist if not using summary.rms, Predict,
# survplot.rms, or if all variable settings are given to them
# options(datadist="dist")
# f <- fitting.function(formula = y ~ rcs(x1,4) + rcs(x2,5) + x1%ia%x2 +
# rcs(x1,4)%ia%rcs(x2,5) +
# strat(sex)*age + strat(race)*bp)
# See rms.trans for rcs, strat, etc.
# %ia% is restricted interaction - not doubly nonlinear
# for x1 by x2 this uses the simple product only, but pools x1*x2
# effect with nonlinear function for overall tests
# specs(f)
# anova(f)
# summary(f)
# fastbw(f)
# pred <- predict(f, newdata=expand.grid(x1=1:10,x2=3,sex="male")
```
#     age=50, race="black")
# pred <- predict(f, newdata=gendata(f, x1=1:10, x2=3, sex="male"))
# This leaves unspecified variables set to reference values from datadist
# pred.combos <- gendata(f, nobs=10) # Use X-windows to edit predictor settings
# predict(f, newdata=pred.combos)
# plot(Predict(f, x1)) # or ggplot(...)  
# latex(f)
# nomogram(f)

Arguments

data a data frame or calling environment
formula model formula
formula2 an optional second model formula (see for example ppo in blrm)
weights a weight variable or expression
subset a subsetting expression evaluated in the calling frame or data
na.action NA handling function, ideally one such as na.delete that stores extra information about data omissions
specials a character vector specifying which function evaluations appearing in formula are "special" in the model.frame sense
dotexpand set to FALSE to prevent . on right hand side of model formula from expanding into all variables in data; used for cph
callenv the parent frame that called the fitting function
mf a model frame
allow.offset set to TRUE if model fitter allows an offset term
intercept 1 if an ordinary intercept is present, 0 otherwise

Value
a data frame augmented with additional information about the predictors and model formulation

Author(s)
Frank Harrell
Department of Biostatistics, Vanderbilt University
fh@fharrell.com

Examples

```r
## Not run:
require(rms)
dist <- datadist(data=2)  # can omit if not using summary, (gg)plot, survplot,
# or if specify all variable values to them. Can
# also defer. data=2: get distribution summaries
# for all variables in search position 2
# run datadist once, for all candidate variables

dist <- datadist(age,race,bp,sex,height)  # alternative
options(datadist="dist")
f <- cph(Surv(d.time, death) ~ rcs(age,4)*strat(race) +
bp*strat(sex)+lsp(height,60),x=TRUE,y=TRUE)

anova(f)
anova(f,age,height)  # Joint test of 2 vars
fastbw(f)
summary(f, sex="female")  # Adjust sex to "female" when testing
# interacting factor bp
bplot(Predict(f, age, height))  # 3-D plot
ggplot(Predict(f, age=10:70, height=60))
latex(f)  # \LaTeX{} representation of fit

f <- lm(y ~ x)  # Can use with any fitting function that
# calls model.frame.default, e.g. lm, glm
specs.rms(f)  # Use .rms since class(f)="lm"
anova(f)  # Works since Varcov(f) (=Varcov.lm(f)) works
fastbw(f)
options(datadist=NULL)
f <- ols(y ~ x1*x2)  # Saves enough information to do fastbw, anova
anova(f)  # Will not do Predict since distributions
fastbw(f)  # of predictors not saved
plot(f, x1=seq(100,300,by=.5), x2=.5)

# all values defined - don't need datadist
options(datadist="dist")
dist <- datadist(x1,x2)  # Equivalent to datadist(f)
plot(f, x1, x2=.5)  # Now you can do plot, summary
plot(nomogram(f, interact=list(x2=c(.2,.7))))

## End(Not run)
```

rms.trans

**rms Special Transformation Functions**

Description

This is a series of functions (`asis`, `pol`, `lsp`, `rcs`, `catg`, `scored`, `strat`, `matrix`, `gTrans`, and `%ia%`) that set up special attributes (such as knots and nonlinear term indicators) that are carried through to fits (using for example `lrm`, `cph`, `ols`, `psm`). `anova.rms`, `summary.rms`, `Predict`, `survplot`, `fastbw`, `validate`, `specs`, `which.influence`, `nomogram` and `latex.rms` use these attributes to automate certain analyses (e.g., automatic tests of linearity for each predictor are done by `anova.rms`).
Many of the functions are called implicitly. Some S functions such as *ns* derive data-dependent transformations that are not always "remembered" when predicted values are later computed, so the predictions may be incorrect. The functions listed here solve that problem when used in the *rms* context.

*asis* is the identity transformation, *pol* is an ordinary (non-orthogonal) polynomial, *rcs* is a linear tail-restricted cubic spline function (natural spline, for which the *rcspline.eval* function generates the design matrix, the presence of system option *rcspc* causes *rcspline.eval* to be invoked with *pc=TRUE*, and the presence of system option *fractied* causes this value to be passed to *rcspline.eval* as the *fractied* argument), *catg* is for a categorical variable, *scored* is for an ordered categorical variable, *strat* is for a stratification factor in a Cox model, *matrix* is for a matrix predictor, and *%ia%* represents restricted interactions in which products involving nonlinear effects on both variables are not included in the model. *asis*, *catg*, *scored*, *matrix* are seldom invoked explicitly by the user (only to specify label or name, usually).

*gTrans* is a general multiple-parameter transformation function. It can be used to specify new polynomial bases, smooth relationships with a discontinuity at one or more values of *x*, grouped categorical variables, e.g., a categorical variable with 5 levels where you want to combine two of the levels to spend only 3 degrees of freedom in all but see plots of predicted values where the two combined categories are kept separate but will have equal effect estimates. The first argument to *gTrans* is a regular numeric, character, or factor variable. The next argument is a function that transforms a vector into a matrix. If the basis functions are to include a linear term it is up to the user to include the original *x* as one of the columns. Column names are assigned automatically, but any column names specified by the user will override the default name. If you want to signal which terms correspond to linear and which correspond to nonlinear effects for the purpose of running *anova.rms*, add an integer vector attribute *nonlinear* to the resulting matrix. This vector specifies the column numbers corresponding to nonlinear effects. The default is to assume a column is a linear effect. The *parms* attribute stored with a *gTrans* result a character vector version of the function, so as to not waste space carrying along any environment information. If you will be using the *latex* method for typesetting the fitted model, you must include a *tex* attribute also in the produced matrix. This must be a function of a single character string argument (that will ultimately contain the name of the predictor in LaTeX notation) and must produce a vector of LaTeX character strings. See [https://hbiostat.org/R/rms/gtrans.html](https://hbiostat.org/R/rms/gtrans.html) for several examples of the use of *gTrans* including the use of *nonlinear* and *tex*.

In the list below, functions *asis* through *gTrans* can have arguments *x*, *parms*, *label*, *name* except that *parms* does not apply to *asis*, *matrix*, *strat*.

**Usage**

```r
asis(...)  
matrix(...)  
pol(...)  
lsp(...)  
rcs(...)  
catg(...)  
scored(...)  
strat(...)  
gTrans(...)  
x1 %ia% x2
```
Arguments

The arguments ... above contain the following.

x  a predictor variable (or a function of one). If you specify e.g. pol(pmin(age,10),3),
a cubic polynomial will be fitted in pmin(age,10) (pmin is the S vector
element–by–element function). The predictor will be labeled age in the
output, and plots with have age in its original units on the axes. If you use a
function such as pmin, the predictor is taken as the first argument, and other
arguments must be defined in the frame in effect when predicted values,
etc., are computed.

parms  parameters of transformation (e.g. number or location of knots). For pol
the argument is the order of the polynomial, e.g. 2 for quadratic (the usual
default). For lsp it is a vector of knot locations (lsp will not estimate knot
locations). For rcs it is the number of knots (if scalar), or vector of knot
locations (if >2 elements). The default number is the nknots system option
if parms is not given. If the number of knots is given, locations are com-
puted for that number of knots. If system option rcspc is TRUE the parms
vector has an attribute defining the principal components transformation
parameters. For catg, parms is the category labels (not needed if variable
is an S category or factor variable). If omitted, catg will use unique(x),
or levels(x) if x is a category or a factor. For scored, parms is a vec-
tor of unique values of variable (uses unique(x) by default). This is not
needed if x is an S ordered variable. For strat, parms is the category
labels (not needed if variable is an S category variable). If omitted, will use
unique(x), or levels(x) if x is category or factor. parms is not used for matrix.

label  label of predictor for plotting (default = "label" attribute or variable
name)

name  Name to use for predictor in model. Default is name of argument to func-
tion.

x1, x2  two continuous variables for which to form a non-doubly-nonlinear interaction

z <- cbind(x, pmax(pmin(x, 20) - 10, 0), x > 20)
attr(z, 'nonlinear') <- 2:3
attr(z, 'tex') <- function(x) sprintf(c('[
    z 
  ]'), x)
gTrans(x, spl)
}
## End(Not run)
Description

These functions are used internally to anova.rms, fastbw, etc., to retrieve various attributes of a design. These functions allow some fitting functions not in the rms series (e.g., lm, glm) to be used with rms.Design, fastbw, and similar functions.

For vcov, there are several functions. The method for orm fits is a bit different because the covariance matrix stored in the fit object only deals with the middle intercept. See the intercepts argument for more options. There is a method for lrm that also allows non-default intercept(s) to be selected (default is first).

The oos.loglik function for each type of model implemented computes the -2 log likelihood for out-of-sample data (i.e., data not necessarily used to fit the model) evaluated at the parameter estimates from a model fit. Vectors for the model’s linear predictors and response variable must be given. oos.loglik is used primarily by bootcov.

The Getlim function retrieves distribution summaries from the fit or from a datadist object. It handles getting summaries from both sources to fill in characteristics for variables that were not defined during the model fit. Getlimi returns the summary for an individual model variable.

Mean is a generic function that creates an R function that calculates the expected value of the response variable given a fit from rms or rmsb.

The related.predictors function returns a list containing variable numbers that are directly or indirectly related to each predictor. The interactions.containing function returns indexes of interaction effects containing a given predictor. The param.order function returns a vector of logical indicators for whether parameters are associated with certain types of effects (nonlinear, interaction, nonlinear interaction). combineRelatedPredictors creates a list of inter-connected main effects and interactions for use with predictrms with type='ccterms' (useful for gIndex).

The Penalty.matrix function builds a default penalty matrix for non-intercept term(s) for use in penalized maximum likelihood estimation. The Penalty.setup function takes a constant or list describing penalty factors for each type of term in the model and generates the proper vector of penalty multipliers for the current model.

logLik.rms returns the maximized log likelihood for the model, whereas AIC.rms returns the AIC. The latter function has an optional argument for computing AIC on a "chi-square" scale (model likelihood ratio chi-square minus twice the regression degrees of freedom. logLik.ols handles the case for ols, just by invoking logLik.lm in the stats package. logLik.Gls is also defined.

nobs.rms returns the number of observations used in the fit.

The lrtest function does likelihood ratio tests for two nested models, from fits that have stats components with "Model L.R." values. For models such as psm, survreg, ols, lm which have scale parameters, it is assumed that scale parameter for the smaller model is fixed at the estimate from the larger model (see the example).

univarLR takes a multivariable model fit object from rms and re-fits a sequence of models containing one predictor at a time. It prints a table of likelihood ratio chi^2 statistics from these fits.

The NewLabels function is used to override the variable labels in a fit object. Likewise, Newlevels can be used to create a new fit object with levels of categorical predictors changed. These two functions are especially useful when constructing nomograms.

rmsArgs handles arguments to functions such as Predict, summary.rms, nomogram so that variables to vary may be specified without values (after an equals sign).
prModFit is the workhorse for the print methods for highest-level rms model fitting functions, handling both regular, html, and LaTeX printing, the latter two resulting in html or LaTeX code written to the console, automatically ready for knitr. The work of printing summary statistics is done by prStats, which uses the Hmisc print.char.matrix function to print overall model statistics if `options(prType=)` was not set to "latex" or "html". Otherwise it generates customized LaTeX or html code. The LaTeX longtable and epic packages must be in effect to use LaTeX.

reListclean allows one to rename a subset of a named list, ignoring the previous names and not concatenating them as R does. It also removes NULL elements and (by default) elements that are NA, as when an optional named element is fetched that doesn’t exist.

formatNP is a function to format a vector of numerics. If digits is specified, formatNP will make sure that the formatted representation has digits positions to the right of the decimal place. If lang="latex" it will translate any scientific notation to LaTeX math form. If lang="html" will convert to html. If pvalue=TRUE, it will replace formatted values with "< 0.0001" (if digits=4).

latex.naprint.delete will, if appropriate, use LaTeX to draw a dot chart of frequency of variable NAs related to model fits. html.naprint.delete does the same thing in the RStudio R markdown context, using Hmisc:dotchartp (which uses plotly) for drawing any needed dot chart.

removeFormulaTerms removes one or more terms from a model formula, using strictly character manipulation. This handles problems such as .terms removing offset() if you subset on anything. The function can also be used to remove the dependent variable(s) from the formula.

Usage

```r
## S3 method for class 'rms'
vcov(object, regcoef.only=TRUE, intercepts='all', ...)
## S3 method for class 'cph'
v cov(object, regcoef.only=TRUE, ...)
## S3 method for class 'Glm'
v cov(object, regcoef.only=TRUE, intercepts='all', ...)
## S3 method for class 'Gls'
v cov(object, intercepts='all', ...)
## S3 method for class 'lrm'
v cov(object, regcoef.only=TRUE, intercepts='all', ...)
## S3 method for class 'ols'
v cov(object, regcoef.only=TRUE, ...)
## S3 method for class 'orm'
v cov(object, regcoef.only=TRUE, intercepts='mid', ...)
## S3 method for class 'psm'
v cov(object, regcoef.only=TRUE, ...)
```

# Given Design attributes and number of intercepts creates R
# format assign list. atr non.slopes Terms
DesignAssign(atr, non.slopes, Terms)

```r
oos.loglik(fit, ...)
```

## S3 method for class 'ols'
oos.loglik(fit, lp, y, ...)
## S3 method for class 'lrm'
oos.loglik(fit, lp, y, ...)

latex(object, file="", append=TRUE, ...)

## S3 method for class 'naprint.delete'
html(object, ...)

removeFormulaTerms(form, which=NULL, delete.response=FALSE)

Arguments

fit result of a fitting function
object result of a fitting function
regcoef.only For fits such as parametric survival models which have a final row and column of the covariance matrix for a non-regression parameter such as a log(scale) parameter, setting regcoef.only=TRUE causes only the first p rows and columns of the covariance matrix to be returned, where p is the length of object$coef.
intercepts set to "none" to omit any rows and columns related to intercepts. Set to an integer scalar or vector to include particular intercept elements. Set to 'all' to include all intercepts, or for orm to "mid" to use the default for orm. The default is to use the first for lrm and the median intercept for orm.
at Design element of a fit
pred index of a predictor variable (main effect)
fit1
fit2 fit objects from lrm, ols, psm, cph etc. It doesn’t matter which fit object is the sub-model.
lp linear predictor vector for oos.loglik. For proportional odds ordinal logistic models, this should have used the first intercept only. If lp and y are omitted, the -2 log likelihood for the original fit are returned.
y values of a new vector of responses passed to oos.loglik.
name the name of a variable in the model
Limval an object returned by Getlim
allow.null prevents Getlim from issuing an error message if no limits are found in the fit or in the object pointed to by options(datadist=)
need.all set to FALSE to prevent Getlim or Getlimi from issuing an error message if data for a variable are not found
type For related.predictors, set to "direct" to return lists of indexes of directly related factors only (those in interactions with the predictor). For AIC.rms, type specifies the basis on which to return AIC. The default is minus twice the maximized log likelihood plus k times the degrees of freedom counting intercept(s).
Specify type='chisq' to get a penalized model likelihood ratio chi-square instead.

term.order 1 for all parameters, 2 for all parameters associated with either nonlinear or interaction effects, 3 for nonlinear effects (main or interaction), 4 for interaction effects, 5 for nonlinear interaction effects.

X a design matrix, not including columns for intercepts

penalty a vector or list specifying penalty multipliers for types of model terms

k the multiplier of the degrees of freedom to be used in computing AIC. The default is 2.

x a result of lrtest, or the result of a high-level model fitting function (for prModFit)

labels a character vector specifying new labels for variables in a fit. To give new labels for all variables, you can specify labels of the form labels=c("Age in Years","Cholesterol"), where the list of new labels is assumed to be the length of all main effect-type variables in the fit and in their original order in the model formula. You may specify a named vector to give new labels in random order or for a subset of the variables, e.g., labels=c(age="Age in Years",chol="Cholesterol"). For prStats, is a list with major column headings, which can themselves be vectors that are then stacked vertically.

levels a list of named vectors specifying new level labels for categorical predictors. This will override parms as well as datadist information (if available) that were stored with the fit.

title a single character string used to specify an overall title for the regression fit, which is printed first by prModFit. Set to "" to suppress the title.

w For prModFit, a special list of lists, which each list element specifying information about a block of information to include in the print. output for a fit. For prStats, w is a list of statistics to print, elements of which can be vectors that are stacked vertically. Unnamed elements specify number of digits to the right of the decimal place to which to round (NA means use format without rounding, as with integers and floating point values). Negative values of digits indicate that the value is a P-value to be formatted with formatNP. Digits are recycled as needed.

digits number of digits to the right of the decimal point, for formatting numeric values in printed output

coops specify coefs=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.

footer a character string to appear at the bottom of the regression model output

file name of file to which to write model output

append specify append=FALSE when using file and you want to start over instead of adding to an existing file.

lang specifies the typesetting language: plain text, LaTeX, or html

lines.page see latex
long set to FALSE to suppress printing of formula and certain other model output

needspace optional character string to insert inside a LaTeX needspace macro call before the statistics table and before the coefficient matrix, to avoid bad page splits. This assumes the LaTeX needspace style is available. Example: needspace='6\baselineskip' or needspace='1.5in'.

subtitle optional vector of character strings containing subtitles that will appear under title but not bolded

na.rm set to FALSE to keep NAs in the vector created by reListclean

pvalue set to TRUE if you want values below 10 to the minus digits to be formatted to be less than that value

form a formula object

which a vector of one or more character strings specifying the names of functions that are called from a formula, e.g., "cluster". By default no right-hand-side terms are removed.

delete.response set to TRUE to remove the dependent variable(s) from the formula

atr, non.slopes, Terms Design function attributes, number of intercepts, and terms object

... other arguments. For reListclean this contains the elements being extracted. For prModFit this information is passed to the Hmisc latexTabular function when a block of output is a vector to be formatted in LaTeX.

Value
vcov returns a variance-covariance matrix oos.loglik returns a scalar -2 log likelihood value. Getlim returns a list with components limits and values, either stored in fit or retrieved from the object created by datadist and pointed to in options(datadist=). related.predictors and combineRelatedPredictors return a list of vectors, and interactions.containing returns a vector. param.order returns a logical vector corresponding to non-strata terms in the model. Penalty.matrix returns a symmetric matrix with dimension equal to the number of slopes in the model. For all but categorical predictor main effect elements, the matrix is diagonal with values equal to the variances of the columns of X. For segments corresponding to c-1 dummy variables for c-category predictors, puts a c-1 x c-1 sub-matrix in Penalty.matrix that is constructed so that a quadratic form with Penalty.matrix in the middle computes the sum of squared differences in parameter values about the mean, including a portion for the reference cell in which the parameter is by definition zero. Newlabels returns a new fit object with the labels adjusted.
reListclean returns a vector of named (by its arguments) elements. formatNP returns a character vector.
removeFormulaTerms returns a formula object.

Description

`rms` is the package that goes along with the book Regression Modeling Strategies. `rms` does regression modeling, testing, estimation, validation, graphics, prediction, and typesetting by storing enhanced model design attributes in the fit. `rms` is a re-written version of the `Design` package that has improved graphics and duplicates very little code in the `survival` package.

The package is a collection of about 180 functions that assist and streamline modeling, especially for biostatistical and epidemiologic applications. It also contains functions for binary and ordinal logistic regression models and the Buckley-James multiple regression model for right-censored responses, and implements penalized maximum likelihood estimation for logistic and ordinary linear models. `rms` works with almost any regression model, but it was especially written to work with logistic regression, Cox regression, accelerated failure time models, ordinary linear models, the Buckley-James model, generalized lease squares for longitudinal data (using the `nlme` package), generalized linear models, and quantile regression (using the `quantreg` package). `rms` requires the Hmisc package to be installed. Note that Hmisc has several functions useful for data analysis (especially data reduction and imputation).

Older references below pertaining to the Design package are relevant to `rms`.

Details

To make use of automatic typesetting features you must have `LaTeX` or one of its variants installed.

Some aspects of `rms` (e.g., `latex`) will not work correctly if `options(contrasts=)` other than `c("contr.treatment", "contr.poly")` are used.

`rms` relies on a wealth of survival analysis functions written by Terry Therneau of Mayo Clinic. Front-ends have been written for several of Therneau's functions, and other functions have been slightly modified.
Statistical Methods Implemented

- Ordinary linear regression models
- Binary and ordinal logistic models (proportional odds and continuation ratio models, probit, log-log, complementary log-log including ordinal cumulative probability models for continuous Y, efficiently handling thousands of distinct Y values using full likelihood methods)
- Bayesian binary and ordinal regression models, partial proportional odds model, and random effects
- Cox model
- Parametric survival models in the accelerated failure time class
- Buckley-James least-squares linear regression model with possibly right-censored responses
- Generalized linear model
- Quantile regression
- Generalized least squares
- Bootstrap model validation to obtain unbiased estimates of model performance without requiring a separate validation sample
- Automatic Wald tests of all effects in the model that are not parameterization-dependent (e.g., tests of nonlinearity of main effects when the variable does not interact with other variables, tests of nonlinearity of interaction effects, tests for whether a predictor is important, either as a main effect or as an effect modifier)
- Graphical depictions of model estimates (effect plots, odds/hazard ratio plots, nomograms that allow model predictions to be obtained manually even when there are nonlinear effects and interactions in the model)
- Various smoothed residual plots, including some new residual plots for verifying ordinal logistic model assumptions
- Composing S functions to evaluate the linear predictor ($X\hat{\beta}$), hazard function, survival function, quantile functions analytically from the fitted model
- Typesetting of fitted model using LaTeX
- Robust covariance matrix estimation (Huber or bootstrap)
- Cubic regression splines with linear tail restrictions (natural splines)
- Tensor splines
- Interactions restricted to not be doubly nonlinear
- Penalized maximum likelihood estimation for ordinary linear regression and logistic regression models. Different parts of the model may be penalized by different amounts, e.g., you may want to penalize interaction or nonlinear effects more than main effects or linear effects
- Estimation of hazard or odds ratios in presence of nonlinearity and interaction
- Sensitivity analysis for an unmeasured binary confounder in a binary logistic model

Motivation

rms was motivated by the following needs:

- need to automatically print interesting Wald tests that can be constructed from the design
- tests of linearity with respect to each predictor
- tests of linearity of interactions
- pooled interaction tests (e.g., all interactions involving race)
- pooled tests of effects with higher order effects
  * test of main effect not meaningful when effect in interaction
  * pooled test of main effect + interaction effect is meaningful
  * test of 2nd-order interaction + any 3rd-order interaction containing those factors is meaningful

• need to store transformation parameters with the fit
  - example: knot locations for spline functions
  - these are "remembered" when getting predictions, unlike standard S or R
  - for categorical predictors, save levels so that same dummy variables will be generated for predictions; check that all levels in out-of-data predictions were present when model was fitted

• need for uniform re-insertion of observations deleted because of NAs when using predict without newdata or when using resid

• need to easily plot the regression effect of any predictor
  - example: age is represented by a linear spline with knots at 40 and 60; plot effect of age on log odds of disease, adjusting interacting factors to easily specified constants
  - vary 2 predictors: plot x1 on x-axis, separate curves for discrete x2 or 3d perspective plot for continuous x2
  - if predictor is represented as a function in the model, plots should be with respect to the original variable:
    f <- lrm(y ~ log(cholesterol)+age)
    plot(Predict(f, cholesterol)) # cholesterol on x-axis, default range
    ggplot(Predict(f, cholesterol)) # same using ggplot2
    plotp(Predict(f, cholesterol)) # same directly using plotly

• need to store summary of distribution of predictors with the fit
  - plotting limits (default: 10th smallest, 10th largest values or %-tiles)
  - effect limits (default: .25 and .75 quantiles for continuous vars.)
  - adjustment values for other predictors (default: median for continuous predictors, most frequent level for categorical ones)
  - discrete numeric predictors: list of possible values example: x=0,1,2,3,5 -> by default don’t plot prediction at x=4
  - values are on the inner-most variable, e.g. cholesterol, not log(chol.)
  - allows estimation/plotting long after original dataset has been deleted
  - for Cox models, underlying survival also stored with fit, so original data not needed to obtain predicted survival curves

• need to automatically print estimates of effects in presence of non-linearity and interaction
  - example: age is quadratic, interacting with sex default effect is inter-quartile-range hazard ratio (for Cox model), for sex=reference level
  - user-controlled effects: summary(fit, age=c(30,50), sex="female") -> odds ratios for logistic model, relative survival time for accelerated failure time survival models
-- effects for all variables (e.g. odds ratios) may be plotted with multiple-confidence-level bars

• need for prettier and more concise effect names in printouts, especially for expanded nonlinear terms and interaction terms
  -- use inner-most variable name to identify predictors
  -- e.g. for \( \min(x^2-3,10) \) refer to factor with legal S-name \( x \)

• need to recognize that an intercept is not always a simple concept
  -- some models (e.g., Cox) have no intercept
  -- some models (e.g., ordinal logistic) have multiple intercepts

• need for automatic high-quality printing of fitted mathematical model (with dummy variables defined, regression spline terms simplified, interactions "factored"). Focus is on regression splines instead of nonparametric smoothers or smoothing splines, so that explicit formulas for fit may be obtained for use outside S. rms can also compose S functions to evaluate \( X\beta \) from the fitted model analytically, as well as compose SAS code to do this.

• need for automatic drawing of nomogram to represent the fitted model

• need for automatic bootstrap validation of a fitted model, with only one S command (with respect to calibration and discrimination)

• need for robust (Huber sandwich) estimator of covariance matrix, and be able to do all other analysis (e.g., plots, C.L.) using the adjusted covariances

• need for robust (bootstrap) estimator of covariance matrix, easily used in other analyses without change

• need for Huber sandwich and bootstrap covariance matrices adjusted for cluster sampling

• need for routine reporting of how many observations were deleted by missing values on each predictor (see \texttt{na.delete} in Hmisc)

• need for optional reporting of descriptive statistics for \( Y \) stratified by missing status of each \( X \) (see \texttt{na.detail.response})

• need for pretty, annotated survival curves, using the same commands for parametric and Cox models

• need for ordinal logistic model (proportional odds model, continuation ratio model)

• need for estimating and testing general contrasts without having to be conscious of variable coding or parameter order

**Fitting Functions Compatible with rms**

rms will work with a wide variety of fitting functions, but it is meant especially for the following:

<table>
<thead>
<tr>
<th>Function</th>

Background for Examples

The following programs demonstrate how the pieces of the rms package work together. A (usually) one-time call to the function datadist requires a pass at the entire data frame to store distribution summaries for potential predictor variables. These summaries contain (by default) the .25 and .75 quantiles of continuous variables (for estimating effects such as odds ratios), the 10th smallest and 10th largest values (or .1 and .9 quantiles for small $n$) for plotting ranges for estimated curves, and the total range. For discrete numeric variables (those having $\leq 10$ unique values), the list of unique values is also stored. Such summaries are used by the summary.rms, Predict, and nomogram.rms functions. You may save time and defer running datadist. In that case, the distribution summary is not stored with the fit object, but it can be gathered before running summary, plot, ggplot, or plotp.

```
d <- datadist(my.data.frame) # or datadist(x1,x2)
options(datadist="d") # omit this or use options(datadist=\nNULL)
if not run datadist yet
  cf <- ols(y ~ x1 * x2)
  anova(f)
  fastbw(f)
  Predict(f, x2) predict(f, newdata)
```

In the Examples section there are three detailed examples using a fitting function designed to be
used with rms, lrm (logistic regression model). In **Detailed Example 1** we create 3 predictor variables and a two binary response on 500 subjects. For the first binary response, dz, the true model involves only sex and age, and there is a nonlinear interaction between the two because the log odds is a truncated linear relationship in age for females and a quadratic function for males. For the second binary outcome, dz.bp, the true population model also involves systolic blood pressure (sys.bp) through a truncated linear relationship. First, nonparametric estimation of relationships is done using the Hmisc package’s plsmo function which uses lowess with outlier detection turned off for binary responses. Then parametric modeling is done using restricted cubic splines. This modeling does not assume that we know the true transformations for age or sys.bp but that these transformations are smooth (which is not actually the case in the population).

For **Detailed Example 2**, suppose that a categorical variable treat has values "a", "b", and "c", an ordinal variable num.diseases has values 0,1,2,3,4, and that there are two continuous variables, age and cholesterol. age is fitted with a restricted cubic spline, while cholesterol is transformed using the transformation \( \log(\text{cholesterol} - 10) \). Cholesterol is missing on three subjects, and we impute these using the overall median cholesterol. We wish to allow for interaction between treat and cholesterol. The following S program will fit a logistic model, test all effects in the design, estimate effects, and plot estimated transformations. The fit for num.diseases really considers the variable to be a 5-level categorical variable. The only difference is that a 3 d.f. test of linearity is done to assess whether the variable can be re-modeled "asis". Here we also show statements to attach the rms package and store predictor characteristics from datadist.

**Detailed Example 3** shows some of the survival analysis capabilities of rms related to the Cox proportional hazards model. We simulate data for 2000 subjects with 2 predictors, age and sex. In the true population model, the log hazard function is linear in age and there is no age \( \times \) sex interaction. In the analysis below we do not make use of the linearity in age. rms makes use of many of Terry Therneau’s survival functions that are builtin to S.

The following is a typical sequence of steps that would be used with rms in conjunction with the Hmisc transcan function to do single imputation of all NAs in the predictors (multiple imputation would be better but would be harder to do in the context of bootstrap model validation), fit a model, do backward stepdown to reduce the number of predictors in the model (with all the severe problems this can entail), and use the bootstrap to validate this stepwise model, repeating the variable selection for each re-sample. Here we take a short cut as the imputation is not repeated within the bootstrap.

In what follows we (atypically) have only 3 candidate predictors. In practice be sure to have the validate and calibrate functions operate on a model fit that contains all predictors that were involved in previous analyses that used the response variable. Here the imputation is necessary because backward stepdown would otherwise delete observations missing on any candidate variable.

Note that you would have to define x1, x2, x3, y to run the following code.

```r
xt <- transcan(~ x1 + x2 + x3, imputed=TRUE)
impute(xt) # imputes any NAs in x1, x2, x3
# Now fit original full model on filled-in data
f <- lrm(y ~ x1 + rcs(x2,4) + x3, x=TRUE, y=TRUE) #x,y allow boot.
fastbw(f)
# derives stepdown model (using default stopping rule)
validate(f, B=100, bw=TRUE) # repeats fastbw 100 times
cal <- calibrate(f, B=100, bw=TRUE) # also repeats fastbw
plot(cal)
```
Common Problems to Avoid

1. Don’t have a formula like \( y \sim \text{age} + \text{age}^2 \). In S you need to connect related variables using a function which produces a matrix, such as \text{pol} or \text{rcs}. This allows effect estimates (e.g., hazard ratios) to be computed as well as multiple d.f. tests of association.

2. Don’t use \text{poly} or \text{strata} inside formulas used in \text{rms}. Use \text{pol} and \text{strat} instead.

3. Almost never code your own dummy variables or interaction variables in S. Let S do this automatically. Otherwise, \text{anova} can’t do its job.

4. Almost never transform predictors outside of the model formula, as then plots of predicted values vs. predictor values, and other displays, would not be made on the original scale. Use instead something like \( y \sim \log(\text{cell.count}+1) \), which will allow \text{cell.count} to appear on \( x \)-axes. You can get fancier, e.g., \( y \sim \text{rcs} (\log(\text{cell.count}+1),4) \) to fit a restricted cubic spline with 4 knots in \( \log(\text{cell.count}+1) \). For more complex transformations do something like

\[
\text{f} \left< = \text{function}(x) \{ \\
\ldots \text{various 'if' statements, etc.} \\
\log(\text{pmin}(x,50000)+1) \\
\} \\
\text{fit1} <- \text{lrm} (\text{death} \sim \text{f} (\text{cell.count} )) \\
\text{fit2} <- \text{lrm} (\text{death} \sim \text{rcs} (\text{f} (\text{cell.count}),4) ) \\
\}
\]

5. Don’t put $ inside variable names used in formulas. Either attach data frames or use \text{data=}.

6. Don’t forget to use \text{datadist}. Try to use it at the top of your program so that all model fits can automatically take advantage if its distributional summaries for the predictors.

7. Don’t validate or calibrate models which were reduced by dropping "insignificant" predictors. Proper bootstrap or cross-validation must repeat any variable selection steps for each re-sample. Therefore, validate or calibrate models which contain all candidate predictors, and if you must reduce models, specify the option \text{bw=}TRUE to validate or calibrate.

8. Dropping of "insignificant" predictors ruins much of the usual statistical inference for regression models (confidence limits, standard errors, \( P \)-values, \( \chi^2 \), ordinary indexes of model performance) and it also results in models which will have worse predictive discrimination.

Accessing the Package

Use \text{require(rms)}.

Published Applications of \text{rms} and Regression Splines

- Spline fits

- Bootstrap calibration curve for a parametric survival model:
• Splines, interactions with splines, algebraic form of fitted model from \texttt{latex.rms}

• Splines, odds ratio chart from fitted model with nonlinear and interaction terms, use of \texttt{transcan} for imputation

• Splines, external validation of logistic models, prediction rules using point tables

• Model fitting, bootstrap validation, missing value imputation

• Model fitting, splines, bootstrap validation, nomograms

• Penalized maximum likelihood estimation, regression splines, web site to get predicted values

• Nomogram with 2- and 5-year survival probability and median survival time (but watch out for the use of univariable screening)

• Comprehensive example of parametric survival modeling with an extensive nomogram, time ratio chart, anova chart, survival curves generated using survplot, bootstrap calibration curve

• Model fitting, imputation, and several nomograms expressed in tabular form

• Ordinal logistic model with bootstrap calibration plot

• Propensity modeling in evaluating medical diagnosis, anova dot chart

• Simulations using rms to study the properties of various modeling strategies

• Statistical methods and references related to rms, along with case studies which includes the rms code which produced the analyses

**Bug Reports**

The author is willing to help with problems. Send E-mail to <fh@fharrell.com>. To report bugs, please do the following:

1. If the bug occurs when running a function on a fit object (e.g., anova), attach a dump’d text version of the fit object to your note. If you used datadist but not until after the fit was created, also send the object created by datadist. Example: save(myfit,"/tmp/myfit.rda") will create an R binary save file that can be attached to the E-mail.

2. If the bug occurs during a model fit (e.g., with lrm, ols, psm, cph), send the statement causing the error with a save’d version of the data frame used in the fit. If this data frame is very large, reduce it to a small subset which still causes the error.

robcov

Robust Covariance Matrix Estimates
Description

Uses the Huber-White method to adjust the variance-covariance matrix of a fit from maximum likelihood or least squares, to correct for heteroscedasticity and for correlated responses from cluster samples. The method uses the ordinary estimates of regression coefficients and other parameters of the model, but involves correcting the covariance matrix for model misspecification and sampling design. Models currently implemented are models that have a `residuals(fit,type="score")` function implemented, such as `lrm`, `cph`, `coxph`, and ordinary linear models (`ols`). The fit must have specified the x=TRUE and y=TRUE options for certain models. Observations in different clusters are assumed to be independent. For the special case where every cluster contains one observation, the corrected covariance matrix returned is the "sandwich" estimator (see Lin and Wei). This is a consistent estimate of the covariance matrix even if the model is misspecified (e.g. heteroscedasticity, underdispersion, wrong covariate form).

For the special case of ols fits, `robcov` can compute the improved (especially for small samples) Efron estimator that adjusts for natural heterogeneity of residuals (see Long and Ervin (2000) estimator HC3).

Usage

```r
robcov(fit, cluster, method=c('huber','efron'))
```

Arguments

- `fit` a fit object from the `rms` series
- `cluster` a variable indicating groupings. `cluster` may be any type of vector (factor, character, integer). NAs are not allowed. Unique values of `cluster` indicate possibly correlated groupings of observations. Note the data used in the fit and stored in `fit$x` and `fit$y` may have had observations containing missing values deleted. It is assumed that if any NAs were removed during the original model fitting, an `naresid` function exists to restore NAs so that the rows of the score matrix coincide with `cluster`. If `cluster` is omitted, it defaults to the integers 1,2,...,n to obtain the "sandwich" robust covariance matrix estimate.
- `method` can set to "efron" for ols fits (only). Default is Huber-White estimator of the covariance matrix.

Value

a new fit object with the same class as the original fit, and with the element `orig.var` added. `orig.var` is the covariance matrix of the original fit. Also, the original `var` component is replaced with the new Huberized estimates. A component `clusterInfo` is added to contain elements `name` and `n` holding the name of the `cluster` variable and the number of clusters.

Rq

rms Package Interface to quantreg Package

Description

The Rq function is the rms front-end to the quantreg package’s rq function. print and latex
methods are also provided, and a fitting function RqFit is defined for use in bootstrapping, etc. Its
result is a function definition.

For the print method, format of output is controlled by the user previously running options(prType="lang")
where lang is "plain" (the default), "latex", or "html". For the latex method, html will actually
be used of options(prType='html').
Usage

Rq(formula, tau = 0.5, data=environment(formula),
    subset, weights, na.action=na.delete,
    method = "br", model = FALSE, contrasts = NULL,
    se = "nid", hs = TRUE, x = FALSE, y = FALSE, ...)

## S3 method for class 'Rq'
print(x, digits=4, coefs=TRUE, title, ...)

## S3 method for class 'Rq'
latex(object,
    file = paste(first.word(deparse(substitute(object))),
        ".tex", sep = ""), append=FALSE,
    which, varnames, columns=65, inline=FALSE, caption=NULL, ...)

## S3 method for class 'Rq'
predict(object, ..., kint=1, se.fit=FALSE)

RqFit(fit, wallow=TRUE, passdots=FALSE)

Arguments

<table>
<thead>
<tr>
<th>Argument</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>formula</td>
<td>model formula</td>
</tr>
<tr>
<td>tau</td>
<td>the single quantile to estimate. Unlike rq you cannot estimate more than one quantile at one model fitting.</td>
</tr>
<tr>
<td>data,subset,weights,na.action,method,model,contrasts,se,hs</td>
<td>see rq</td>
</tr>
<tr>
<td>x</td>
<td>set to TRUE to store the design matrix with the fit. For print is an Rq object.</td>
</tr>
<tr>
<td>y</td>
<td>set to TRUE to store the response vector with the fit</td>
</tr>
<tr>
<td>...</td>
<td>other arguments passed to one of the rq fitting routines. For latex.Rq these are optional arguments passed to latexrms. Ignored for print.Rq. For predict.Rq this is usually just a newdata argument.</td>
</tr>
<tr>
<td>digits</td>
<td>number of significant digits used in formatting results in print.Rq.</td>
</tr>
<tr>
<td>coefs</td>
<td>specify coefs=FALSE to suppress printing the table of model coefficients, standard errors, etc. Specify coefs=n to print only the first n regression coefficients in the model.</td>
</tr>
<tr>
<td>title</td>
<td>a character string title to be passed to prModFit</td>
</tr>
<tr>
<td>object</td>
<td>an object created by Rq</td>
</tr>
<tr>
<td>file,append,which,varnames,columns,inline,caption</td>
<td>see latexrms</td>
</tr>
<tr>
<td>kint</td>
<td>ignored</td>
</tr>
<tr>
<td>se.fit</td>
<td>set to TRUE to obtain standard errors of predicted quantiles</td>
</tr>
<tr>
<td>fit</td>
<td>an object created by Rq</td>
</tr>
<tr>
<td>wallow</td>
<td>set to TRUE if weights are allowed in the current context.</td>
</tr>
<tr>
<td>passdots</td>
<td>set to TRUE if...may be passed to the fitter</td>
</tr>
</tbody>
</table>
Value

Rq returns a list of class "rms", "lassorq" or "scadrq", "Rq", and "rq". RqFit returns a function definition. latex.Rq returns an object of class "latex".

Note

The author and developer of methodology in the quantreg package is Roger Koenker.

  llines(x, exp(x + qnorm(.75)/4), col=col[2], lty=2)
}
plot(p, addpanel=a)
## End(Not run)
```

sensuc  Sensitivity to Unmeasured Covariables
Description

Performs an analysis of the sensitivity of a binary treatment ($X$) effect to an unmeasured binary confounder ($U$) for a fitted binary logistic or an unstratified non-time-dependent Cox survival model (the function works well for the former, not so well for the latter). This is done by fitting a sequence of models with separately created $U$ variables added to the original model. The sequence of models is formed by simultaneously varying $a$ and $b$, where $a$ measures the association between $U$ and $X$ and $b$ measures the association between $U$ and $Y$, where $Y$ is the outcome of interest. For Cox models, an approximate solution is used by letting $Y$ represent some binary classification of the event/censoring time and the event indicator. For example, $Y$ could be just the event indicator, ignoring time of the event or censoring, or it could be 1 if a subject failed before one year and 0 otherwise. When for each combination of $a$ and $b$ the vector of binary values $U$ is generated, one of two methods is used to constrain the properties of $U$. With either method, the overall prevalence of $U$ is constrained to be $\text{prev.} u$. With the default method ($\text{or.method} = "x:u y:u"$), $U$ is sampled so that the $X : U$ odds ratio is $a$ and the $Y : U$ odds ratio is $b$. With the second method, $U$ is sampled according to the model $\logit(U = 1 | X, Y) = \alpha + \beta Y + \gamma X$, where $\beta = \log(b)$ and $\gamma = \log(a)$ and $\alpha$ is determined so that the prevalence of $U = 1$ is $\text{prev.} u$. This second method results in the adjusted odds ratio for $Y : U$ given $X$ being $b$ whereas the default method forces the unconditional (marginal) $Y : U$ odds ratio to be $b$. Rosenbaum uses the default method.

There is a plot method for plotting objects created by sensuc. Values of $a$ are placed on the x-axis and observed marginal odds or hazards ratios for $U$ (unadjusted ratios) appear on the y-axis. For Cox models, the hazard ratios will not agree exactly with $X$ : event indicator odds ratios but they sometimes be made close through judicious choice of the event function. The default plot uses four symbols which differentiate whether for the $a,b$ combination the effect of $X$ adjusted for $U$ (and for any other covariables that were in the original model fit) is positive (usually meaning an effect ratio greater than 1) and "significant", merely positive, not positive and non significant, or not positive but significant. There is also an option to draw the numeric value of the $X$ effect ratio at the $a,b$ combination along with its Z statistic underneath in smaller letters, and an option to draw the effect ratio in one of four colors depending on the significance of the $Z$ statistic.

Usage

```r
# fit <- lrm(formula=y ~ x + other.predictors, x=TRUE, y=TRUE)  # or
# fit <- cph(formula=Surv(event.time,event.indicator) ~ x + other.predictors,
#    x=TRUE, y=TRUE)
sensuc(fit,
    or.xu=seq(1, 6, by = 0.5), or.u=or.xu,
    prev.u=0.5, constrain.binary.sample=TRUE,
    or.method=c("x:u y:u","u|x,y"),
    event=function(y) if(is.matrix(y))y[,ncol(y)] else 1*y)
## S3 method for class 'sensuc'
plot(x, ylim=c((1+trunc(min(x$effect.u)-.01))/
    ifelse(type=='numbers',2,1),
    1+trunc(max(x$effect.u)-.01)),$
    xlab='Odds Ratio for X:U',
ylab=if(x$type=='lrm')'Odds Ratio for Y:U' else
' Hazard Ratio for Y:U',
```
digits=2, cex.effect=.75, cex.z=.6*cex.effect,
delta=diff(par('usr')[3:4])/40,
type=c('symbols','numbers','colors'),
pch=c(15,18,5,0), col=c(2,3,1,4), alpha=.05,
impressive.effect=function(x)x > 1,...)

Arguments

fit         result of lrm or cph with x=TRUE, y=TRUE. The first variable in the right hand side of the model formula must have been the binary X variable, and it may not interact with other predictors.
x          result of sensuc
or.xu       vector of possible odds ratios measuring the X : U association.
or.u        vector of possible odds ratios measuring the Y : U association. Default is or.xu.
prev.u      desired prevalence of U = 1. Default is 0.5, which is usually a "worst case" for sensitivity analyses.
constrain.binary.sample
By default, the binary U values are sampled from the appropriate distributions conditional on Y and X so that the proportions of U = 1 in each sample are exactly the desired probabilities, to within the closeness of n×probability to an integer. Specify constrain.binary.sample=FALSE to sample from ordinary Bernoulli distributions, to allow proportions of U = 1 to reflect sampling fluctuations.
or.method   see above
event       a function classifying the response variable into a binary event for the purposes of constraining the association between U and Y. For binary logistic models, event is left at its default value, which is the identify function, i.e, the original Y values are taken as the events (no other choice makes any sense here). For Cox models, the default event function takes the last column of the Surv object stored with the fit. For rare events (high proportion of censored observations), odds ratios approximate hazard ratios, so the default is OK. For other cases, the survival times should be considered (probably in conjunction with the event indicators), although it may not be possible to get a high enough hazard ratio between U and Y by sampling U by temporarily making Y binary. See the last example which is for a 2-column Surv object (first column of response variable=event time, second=event indicator). When dichotomizing survival time at a given point, it is advantageous to choose the cutpoint so that not many censored survival times preceed the cutpoint. Note that in fitting Cox models to examine sensitivity to U, the original non-dichotomized failure times are used.
ylim        y-axis limits for plot
xlab        x-axis label
ylab        y-axis label
digits      number of digits to the right of the decimal point for drawing numbers on the plot, for type="numbers" or type="colors".
sensuc

- **cex.effect**: character size for drawing effect ratios
- **cex.z**: character size for drawing Z statistics
- **delta**: decrement in y value used to draw Z values below effect ratios
- **type**: specify "symbols" (the default), "numbers", or "colors" (see above)
- **pch**: 4 plotting characters corresponding to positive and significant effects for X, positive and non-significant effects, not positive and not significant, not positive but significant
- **col**: 4 colors as for pch
- **alpha**: significance level
- **impressive.effect**: a function of the odds or hazard ratio for X returning TRUE for a positive effect. By default, a positive effect is taken to mean a ratio exceeding one.

... optional arguments passed to plot

**Value**

sensuc returns an object of class "sensuc" with the following elements: OR.xu (vector of desired X : U odds ratios or a values), OOR.xu (observed marginal X : U odds ratios), OR.u (desired Y : U odds ratios or b values), effect.x (adjusted odds or hazards ratio for X in a model adjusted for U and all of the other predictors), effect.u (unadjusted Y : U odds or hazards ratios), effect.u.adj (adjusted Y : U odds or hazards ratios), Z (Z-statistics), prev.u (input to sensuc), cond.prev.u (matrix with one row per a,b combination, specifying prevalences of U conditional on Y and X combinations), and type ("lrm" or "cph").

y <- sample(0:1, 500, TRUE)
y[1:100] <- x[1:100] # induce an association between x and y
x2 <- rnorm(500)

f <- lrm(y ~ x + x2, x=TRUE, y=TRUE)
#Note: in absence of U odds ratio for x is exp(2nd coefficient)

g <- sensuc(f, c(1,3))
# Note: If the generated sample of U was typical, the odds ratio for
# x dropped had U been known, where U had an odds ratio
# with x of 3 and an odds ratio with y of 3

plot(g)

# Fit a Cox model and check sensitivity to an unmeasured confounder

# f <- cph(Surv(d.time,death) ~ treatment + pol(age,2)*sex, x=TRUE, y=TRUE)
# sensuc(f, event=function(y) y[,2] & y[,1] < 365.25 )
# Event = failed, with event time before 1 year
# Note: Analysis uses f$y which is a 2-column Surv object
```

**setPb**  
*Progress Bar for Simulations*

**Description**

Depending on prevailing `options(showprogress=)` and availability of the tcltk package, sets up a progress bar and creates a function for simple updating of the bar as iterations progress. Setting `options(showprogressbar=FALSE)` or `options(showprogressbar='none')` results in no progress being shown. Setting the option to something other than "tk" or "none" results in the console being used to show the current iteration number and intended number of iterations, the same as if tcltk is not installed. It is not recommended that the "tk" be used for simulations requiring fewer than 10 seconds for more than 100 iterations, as the time required to update the pop-up window will be more than the time required to do the simulations. This problem can be solved by specifying, for example, every=10 to `setPb` or to the function created by `setPb`, or by using `options(showevery=10)` before `setPb` is called. If `options(showprogress=)` is not specified, progress is shown in the console with an iteration counter.
setPb

Usage

setPb(n, type = c("Monte Carlo Simulation", "Bootstrap", "Cross-Validation"),
label, usetk = TRUE, onlytk = FALSE, every = 1)

Arguments

n maximum number of iterations

type type of simulation. Used for the progress bar title if tcltk is being used.

label used to customize the bar label if present, overriding type

usetk set to FALSE to override, acting as though the tcltk package were not installed

onlytk set to TRUE to not write to the console even if tcltk is unavailable and showprogressbar is not FALSE or "none"

every print a message for every every iterations

Value

a function that should be called by the user once per iteration, specifying the iteration number as the sole argument

Author(s)

Frank Harrell

```r
## Not run:
options(showprogress=TRUE) # same as='tk'
pb <- setPb(1000)
for(i in 1:1000) {
  pb(i) # pb(i, every=10) to only show for multiples of 10
  # your calculations
}
# Force rms functions to do simulations to not report progress
options(showprogress='none')
# For functions that do simulations to use the console instead of pop-up
# Even with tcltk is installed
options(showprogress='console')
pb <- setPb(1000, label='Random Sampling')
## End(Not run)
```
Description

Prints the design specifications, e.g., number of parameters for each factor, levels of categorical factors, knot locations in splines, pre-transformations, etc.

Usage

```r
specs(fit, ...)  # S3 method for class 'rms'
specs(fit, long=FALSE, ...)
```

# S3 method for class 'specs.rms'
print(x, ...)

Arguments

- `fit`: a fit object created with the `rms` library in effect
- `x`: an object returned by `specs`
- `long`: if `TRUE`, causes the plotting and estimation limits to be printed for each factor
- `...`: ignored

Value

- a list containing information about the fit and the predictors as elements

sick <- ifelse(runif(200) <= plogis(L), 1, 0)
f <- lrm(sick ~ rcs(blood.pressure,5))
```
summary.rms

specsf # find out where 5 knots are placed
g <- glm(sick ~ rcs(blood.pressure,5), family=binomial)
specs(g, long=TRUE)
options(datadist=NULL)

summary.rms

Summary of Effects in Model

Description

summary.rms forms a summary of the effects of each factor. When summary is used to estimate
odds or hazard ratios for continuous variables, it allows the levels of interacting factors to be easily
set, as well as allowing the user to choose the interval for the effect. This method of estimating
effects allows for nonlinearity in the predictor. Factors requiring multiple parameters are handled,
as summary obtains predicted values at the needed points and takes differences. By default, inter-
quartile range effects (odds ratios, hazards ratios, etc.) are printed for continuous factors, and all
comparisons with the reference level are made for categorical factors. print.summary.rms prints
the results, latex.summary.rms and html.summary.rms typeset the results, and plot.summary.rms
plots shaded confidence bars to display the results graphically. The longest confidence bar on each
page is labeled with confidence levels (unless this bar has been ignored due to clip). By default,
the following confidence levels are all shown: .9, .95, and .99, using blue of different transparen-
cies. The plot method currently ignores bootstrap and Bayesian highest posterior density intervals
but approximates intervals based on standard errors. The html method is for use with R Markdown
using html.

The print method will call the latex or html method if options(prType=) is set to "latex" or
"html". For "latex" printing through print(), the LaTeX table environment is turned off.
If usebootcoef=TRUE and the fit was run through bootcov, the confidence intervals are bootstrap nonparametric percentile confidence intervals, basic bootstrap, or BCa intervals, obtained on con-
trasts evaluated on all bootstrap samples.
If options(grType='plotly') is in effect and the plotly package is installed, plot is used in-
stead of base graphics to draw the point estimates and confidence limits when the plot method for
summary is called. Colors and other graphical arguments to plot.summary are ignored in this case.
Various special effects are implemented such as only drawing 0.95 confidence limits by default but
including a legend that allows the other CLs to be activated. Hovering over point estimates shows
adjustment values if there are any. nbar is not implemented for plotly.

Usage

## S3 method for class 'rms'
summary(object, ..., ycut=NULL, est.all=TRUE, antilog,
conf.int=.95, abbrev=FALSE, vnames=c("names","labels"),
conf.type=c('individual','simultaneous'),
usebootcoef=TRUE, boot.type=c("percentile","bca","basic"),
posterior.summary=c('mean', 'median', 'mode'), verbose=FALSE)

## S3 method for class 'summary.rms'
print(x, ..., table.env=FALSE)

## S3 method for class 'summary.rms'
latex(object, title, table.env=TRUE, ...)

## S3 method for class 'summary.rms'
html(object, digits=4, dec=NULL, ...)

## S3 method for class 'summary.rms'
plot(x, at, log=FALSE,
    q=c(0.9, 0.95, 0.99), xlim, nbar, cex=1, nint=10,
    cex.main=1, clip=c(-1e30,1e30), main,
    col=rgb(red=.1,green=.1,blue=.8,alpha=c(.1,.4,.7)),
    col.points=rgb(red=.1,green=.1,blue=.8,alpha=1), pch=17,
    lwd=if(length(q) == 1) 3 else 2 : (length(q) + 1), digits=4, ...)

Arguments

object

A rms fit object. Either options(datadist) should have been set before the fit,
or datadist() and options(datadist) run before summary. For latex is the
result of summary.

... For summary, omit list of variables to estimate effects for all predictors. Use a
list of variables of the form age, sex to estimate using default ranges. Specify
age=50 for example to adjust age to 50 when testing other factors (this will
only matter for factors that interact with age). Specify e.g. age=c(40,60) to
estimate the effect of increasing age from 40 to 60. Specify age=c(40,50,60)
to let age range from 40 to 60 and be adjusted to 50 when testing other inter-
acting factors. For category factors, a single value specifies the reference
cell and the adjustment value. For example, if treat has levels "a", "b" and "c"
and treat="b" is given to summary, treatment a will be compared to b and c
will be compared to b. Treatment b will be used when estimating the effect of
other factors. Category variables can have category labels listed (in quotes), or
an unquoted number that is a legal level, if all levels are numeric. You need only
use the first few letters of each variable name - enough for unique identification.
For variables not defined with datadist, you must specify 3 values, none of
which are NA.

Also represents other arguments to pass to latex, is ignored for print and plot.

ycut

Must be specified if the fit is a partial proportional odds model. Specifies the
single value of the response variable used to estimate ycut-specific regression
effects, e.g., odds ratios

est.all

Set to FALSE to only estimate effects of variables listed. Default is TRUE.

antilog

Set to FALSE to suppress printing of anti-logged effects. Default is TRUE if the
model was fitted by lrmm or cph. Antilogged effects will be odds ratios for logis-
tic models and hazard ratios for proportional hazards models.

conf.int

Defaults to .95 for 95% confidence intervals of effects.

abbrev

Set to TRUE to use the abbreviate function to shorten factor levels for categor-
ical variables in the model.
vnames Set to "labels" to use variable labels to label effects. Default is "names" to use variable names.

conf.type The default type of confidence interval computed for a given individual (1 d.f.) contrast is a pointwise confidence interval. Set conf.type="simultaneous" to use the multcomp package's glht and confint functions to compute confidence intervals with simultaneous (family-wise) coverage, thus adjusting for multiple comparisons. Contrasts are simultaneous only over groups of intervals computed together.

usebootcoef If fit was the result of bootcov but you want to use the bootstrap covariance matrix instead of the nonparametric percentile, basic, or BCa methods for confidence intervals (which uses all the bootstrap coefficients), specify usebootcoef=FALSE.

boot.type set to 'bcabca' to compute BCa confidence limits or to 'basic' to use the basic bootstrap. The default is to compute percentile intervals.

prior.sampling

set to 'mode' or 'median' to use the posterior mean/median instead of the mean for point estimates of contrasts

verbose set to TRUE when conf.type='simultaneous' to get output describing scope of simultaneous adjustments

x result of summary

title title to pass to latex. Default is name of fit object passed to summary prefixed with "summary".

table.env see \texttt{latex}

digits,dec for \texttt{html.summary.rms}; digits is the number of significant digits for printing for effects, standard errors, and confidence limits. It is ignored if dec is given. The statistics are rounded to dec digits to the right of the decimal point of dec is given. digits is also the number of significant digits to format numeric hover text and labels for plotly.

at vector of coordinates at which to put tick mark labels on the main axis. If log=TRUE, at should be in anti-log units.

log Set to TRUE to plot on $X_\beta$ scale but labeled with anti-logs.

q scalar or vector of confidence coefficients to depict

xlim X-axis limits for plot in units of the linear predictors (log scale if log=TRUE). If at is specified and xlim is omitted, xlim is derived from the range of at.

nbar Sets up plot to leave room for nbar horizontal bars. Default is the number of non-interaction factors in the model. Set nbar to a larger value to keep too much surrounding space from appearing around horizontal bars. If nbar is smaller than the number of bars, the plot is divided into multiple pages with up to nbar bars on each page.

cex cex parameter for factor labels.

nint Number of tick mark numbers for pretty.

cex.main cex parameter for main title. Set to 0 to suppress the title.

clip confidence limits outside the interval $c(\text{clip}[1], \text{clip}[2])$ will be ignored, and clip also be respected when computing xlim when xlim is not specified. clip should be in the units of $f(x)$. If log=TRUE, clip should be in $X_\beta$ units.
main

main title. Default is inferred from the model and value of log, e.g., "log Odds Ratio".

col

vector of colors, one per value of q

col.points

color for points estimates

pch

symbol for point estimates. Default is solid triangle.

lwd

line width for confidence intervals, corresponding to q

Value

For summary.rms, a matrix of class summary.rms with rows corresponding to factors in the model and columns containing the low and high values for the effects, the range for the effects, the effect point estimates (difference in predicted values for high and low factor values), the standard error of this effect estimate, and the lower and upper confidence limits. If fit$scale.pred has a second level, two rows appear for each factor, the second corresponding to anti–logged effects. Non–categorical factors are stored first, and effects for any categorical factors are stored at the end of the returned matrix. scale.pred and adjust. adjust is a character string containing levels of adjustment variables, if there are any interactions. Otherwise it is "". latex.summary.rms returns an object of class c("latex", "file"). It requires the latex function in Hmisc.

options(datadist=NULL)

---

**survest.cph  Cox Survival Estimates**

**Description**

Compute survival probabilities and optional confidence limits for Cox survival models. If \( x=TRUE \), \( y=TRUE \) were specified to \texttt{cph}, confidence limits use the correct formula for any combination of predictors. Otherwise, if \texttt{surv=TRUE} was specified to \texttt{cph}, confidence limits are based only on standard errors of \( \log(S(t)) \) at the mean value of \( X\beta \). If the model contained only stratification factors, or if predictions are being requested near the mean of each covariable, this approximation will be accurate. Unless times is given, at most one observation may be predicted.
Usage

survest(fit, ...)  
## S3 method for class 'cph'
survest(fit, newdata, linear.predictors, x, times,  
  fun, loglog=FALSE, conf.int=0.95, type, vartype,  
  conf.type=c("log", "log-log", "plain", "none"), se.fit=TRUE,  
  what=c('survival','parallel'),  
  individual=FALSE, ...)  

Arguments

fit a model fit from cph
newdata a data frame containing predictor variable combinations for which predictions are desired
linear.predictors a vector of linear predictor values (centered) for which predictions are desired. If the model is stratified, the "strata" attribute must be attached to this vector (see example).
x a design matrix at which to compute estimates, with any strata attached as a "strata" attribute. Only one of newdata, linear.predictors, or x may be specified. If none is specified, but times is specified, you will get survival predictions at all subjects' linear predictor and strata values.
times a vector of times at which to get predictions. If omitted, predictions are made at all unique failure times in the original input data.
loglog set to TRUE to make the log-log transformation of survival estimates and confidence limits.
fun any function to transform the estimates and confidence limits (loglog is a special case)
conf.int set to FALSE or 0 to suppress confidence limits, or e.g. .95 to cause 0.95 confidence limits to be computed
type see survfit.coxph
vartype see survfit.coxph
conf.type specifies the basis for computing confidence limits. "log" is the default as in the survival package.
se.fit set to TRUE to get standard errors of log predicted survival (no matter what conf.type is). If FALSE, confidence limits are suppressed.
individual set to TRUE to have survfit interpret newdata as specifying a covariable path for a single individual (represented by multiple records).
what Normally use what="survival" to estimate survival probabilities at times that may not correspond to the subjects' own times. what="parallel" assumes that the length of times is the number of subjects (or one), and causes survest to estimate the ith subject's survival probability at the ith value of times (or at the scalar value of times). what="parallel" is used by val.surv for example.

... unused
Details

The result is passed through naresid if newdata, linear.predictors, and x are not specified, to restore placeholders for NAs.

Value

If times is omitted, returns a list with the elements time, n.risk, n.event, surv, call (calling statement), and optionally std.err, upper, lower, conf.type, conf.int. The estimates in this case correspond to one subject. If times is specified, the returned list has possible components time, surv, std.err, lower, and upper. These will be matrices (except for time) if more than one subject is being predicted, with rows representing subjects and columns representing times. If times has only one time, these are reduced to vectors with the number of elements equal to the number of subjects.

options(datadist=NULL)

---

survest.psm  
*Parametric Survival Estimates*

**Description**

Computes predicted survival probabilities or hazards and optionally confidence limits (for survival only) for parametric survival models fitted with psm. If getting predictions for more than one observation, times must be specified. For a model without predictors, no input data are specified.

**Usage**

```r
## S3 method for class 'psm'
survest(fit, newdata, linear.predictors, x, times, fun, 
        loglog=FALSE, conf.int=0.95, 
        what=c("survival","hazard","parallel"), ...)

## S3 method for class 'survest.psm'
print(x, ...)
```

**Arguments**

- `fit`  
  fit from psm
- `newdata, linear.predictors, x, times, conf.int`  
  see survest.cph. One of newdata, linear.predictors, x must be given. 
  linear.predictors includes the intercept. If times is omitted, predictions are made at 200 equally spaced points between 0 and the maximum failure/censoring time used to fit the model.
  x can also be a result from survest.psm.
survest.psm

what
The default is to compute survival probabilities. Set what="hazard" or some abbreviation of "hazard" to compute hazard rates. what="parallel" assumes that the length of times is the number of subjects (or one), and causes survest to estimate the $i^{th}$ subject's survival probability at the $i^{th}$ value of times (or at the scalar value of times). what="parallel" is used by val.surv for example.

loglog
set to TRUE to transform survival estimates and confidence limits using log-log

fun
a function to transform estimates and optional confidence intervals

... unused

Details
Confidence intervals are based on asymptotic normality of the linear predictors. The intervals account for the fact that a scale parameter may have been estimated jointly with beta.

Value
see survest.cph. If the model has no predictors, predictions are made with respect to varying time only, and the returned object is of class "npsurv" so the survival curve can be plotted with survplot.npsurv. If times is omitted, the entire survival curve or hazard from t=0,...,fit$maxtime$ is estimated, with increments computed to yield 200 points where fit$maxtime$ is the maximum survival time in the data used in model fitting. Otherwise, the times vector controls the time points used.

survest(f, data.frame(age=40), what="hazard")$surv # still called surv

survfit.cph

Cox Predicted Survival

Description

This is a slightly modified version of Therneau's survfit.coxph function. The difference is that survfit.cph assumes that x=TRUE, y=TRUE were specified to the fit. This assures that the environment in effect at the time of the fit (e.g., automatic knot estimation for spline functions) is the same one used for basing predictions.

Usage

## S3 method for class 'cph'
survfit(formula, newdata, se.fit=TRUE, conf.int=0.95,
        individual=FALSE, type=NULL, vartype=NULL,
        conf.type=c('log', "log-log", "plain", "none"), id, ...)

Arguments

formula a fit object from cph or coxph see survfit.coxph
newdata, se.fit, conf.int, individual, type, vartype, conf.type, id
see survfit. If individual is TRUE, there must be exactly one Surv object
in newdata. This object is used to specify time intervals for time-dependent
covariate paths. To get predictions for multiple subjects with time-dependent
covariates, specify a vector id which specifies unique hypothetical subjects. The
length of id should equal the number of rows in newdata.

... Not used

Value

see survfit.coxph

survest.cph
survplot

Plot Survival Curves and Hazard Functions

Description

Plot estimated survival curves, and for parametric survival models, plot hazard functions. There is an option to print the number of subjects at risk at the start of each time interval. Curves are automatically labeled at the points of maximum separation (using the labcurve function), and there are many other options for labeling that can be specified with the label.curves parameter. For example, different plotting symbols can be placed at constant x-increments and a legend linking the symbols with category labels can automatically positioned on the most empty portion of the plot.

For the case of a two stratum analysis by npsurv, survdiffplot plots the difference in two Kaplan-Meier estimates along with approximate confidence bands for the differences, with a reference line at zero. The number of subjects at risk is optionally plotted. This number is taken as the minimum of the number of subjects at risk over the two strata. When conf='diffbands', survdiffplot instead does not make a new plot but adds a shaded polygon to an existing plot, showing the midpoints of two survival estimates plus or minus 1/2 the width of the confidence interval for the difference of two Kaplan-Meier estimates.

survplotp creates an interactive plotly graphic with shaded confidence bands. In the two strata case, it draws the 1/2 confidence bands for the difference in two probabilities centered at the midpoint of the probability estimates, so that where the two curves touch this band there is no significant difference (no multiplicity adjustment is made). For the two strata case, the two individual confidence bands have entries in the legend but are not displayed until the user clicks on the legend.

When code was from running npsurv on a multi-state/competing risk Surv object, survplot plots cumulative incidence curves properly accounting for competing risks. You must specify exactly one state/event cause to plot using the state argument. survplot will not plot multiple states on one graph. This can be accomplished using multiple calls with different values of state and specifying add=TRUE for all but the first call.

Usage

survplot(fit, ...)  
survplotp(fit, ...)  
## S3 method for class 'rms'

  srt.n.risk=0, adj.n.risk=1,
y.n.risk, cex.n.risk=.6, cex.xlab=par('cex.lab'),
cex.ylab=cex.xlab, convert=function(f) f)

Arguments

fit        result of fit (cph, psm, npsurv, survvest.psm). For survdiffplot, fit must be
            the result of npsurv.

...        list of factors with names used in model. For fits from npsurv these arguments
do not appear - all strata are plotted. Otherwise the first factor listed is the factor
used to determine different survival curves. Any other factors are used to specify
single constants to be adjusted to, when defaults given to fitting routine (through
limits) are not used. The value given to factors is the original coding of data
given to fit, except that for categorical or strata factors the text string levels
may be specified. The form of values given to the first factor are none (omit the equal
sign to use default range or list of all values if variable is discrete), "text" if
factor is categorical, c(value1, value2, ...), or a function which returns a
vector, such as seq(low,high,by=increment). Only the first factor may have
the values omitted. In this case the Low effect, Adjust to, and High effect
values will be used from datadist if the variable is continuous. For variables
survplot

not defined to datadist, you must specify non-missing constant settings (or a vector of settings for the one displayed variable). Note that since npsurv objects do not use the variable list in ..., you can specify any extra arguments to labcurve by adding them at the end of the list of arguments. For survplotp ...(e.g., height, width) is passed to plotly::plot_ly.

xlim a vector of two numbers specifying the x-axis range for follow-up time. Default is \((0, \text{maxtime})\) where maxtime was the pretty(d) version of the maximum follow-up time in any stratum, stored in fit$maxtime. If logt=TRUE, default is \((1, \log(\text{maxtime}))\).

ylim y-axis limits. Default is \(c(0,1)\) for survival, and \(c(-5,1.5)\) if loglog=TRUE. If fun or loglog=TRUE are given and ylim is not, the limits will be computed from the data. For what="hazard", default limits are computed from the first hazard function plotted.

xlab x-axis label. Default is units attribute of failure time variable given to Surv.

ylab y-axis label. Default is "Survival Probability" or "log(-log Survival Probability)". If fun is given, the default is ".". For what="hazard", the default is "Hazard Function". For a multi-state/competing risk application the default is "Cumulative Incidence".

time.inc time increment for labeling the x-axis and printing numbers at risk. If not specified, the value of time.inc stored with the model fit will be used.

state the state/event cause to use in plotting if the fit was for a multi-state/competing risk Surv object

type specifies type of estimates, "tsiatis" (the default) or "kaplan-meier". "tsiatis" here corresponds to the Breslow estimator. This is ignored if survival estimates stored with surv=TRUE are being used. For fits from npsurv, this argument is also ignored, since it is specified as an argument to npsurv.

conf.type specifies the basis for confidence limits. This argument is ignored for fits from npsurv.

conf.int Default is FALSE. Specify e.g., .95 to plot 0.95 confidence bands. For fits from parametric survival models, or Cox models with x=TRUE and y=TRUE specified to the fit, the exact asymptotic formulas will be used to compute standard errors, and confidence limits are based on \(\log(-\log S(t))\) if loglog=TRUE. If x=TRUE and y=TRUE were not specified to cph but surv=TRUE was, the standard errors stored for the underlying survival curve(s) will be used. These agree with the former if predictions are requested at the mean value of X beta or if there are only stratification factors in the model. This argument is ignored for fits from npsurv, which must have previously specified confidence interval specifications. For survdiffplot if conf.int is not specified, the level used in the call to npsurv will be used.

conf "bars" for confidence bars at each time.inc time point. If the fit was from cph(..., surv=TRUE), the time.inc used will be that stored with the fit. Use conf="bands" (the default) for bands using standard errors at each failure time. For npsurv objects only, conf may also be "none", indicating that confidence interval information stored with the npsurv result should be ignored. For npsurv and survdiffplot, conf may be "diffbands" whereby a shaded region is drawn for comparing two curves. The polygon is centered at the midpoint of
the two survival estimates and the height of the polygon is 1/2 the width of the approximate conf.int pointwise confidence region. Survival curves not overlapping the shaded area are approximately significantly different at the 1 - conf.int level.

mylim
used to curtail computed ylim. When ylim is not given by the user, the computed limits are expanded to force inclusion of the values specified in mylim.

what
defaults to "survival" to plot survival estimates. Set to "hazard" or an abbreviation to plot the hazard function (for psm fits only). Confidence intervals are not available for what="hazard".

add
set to TRUE to add curves to an existing plot.

label.curves
default is TRUE to use labcurve to label curves where they are farthest apart. Set label.curves to a list to specify options to labcurve, e.g., label.curves=list(method="arrow", cex=.8). These option names may be abbreviated in the usual way arguments are abbreviated. Use for example label.curves=list(keys=1:5) to draw symbols (as in pch=1:5 - see points) on the curves and automatically position a legend in the most empty part of the plot. Set label.curves=FALSE to suppress drawing curve labels. The col, lty, lwd, and type parameters are automatically passed to labcurve, although you can override them here. To distinguish curves by line types and still have labcurve construct a legend, use for example label.curves=list(keys="lines"). The negative value for the plotting symbol will suppress a plotting symbol from being drawn either on the curves or in the legend.

abbrev.label
set to TRUE to abbreviate() curve labels that are plotted

levels.only
set to TRUE to remove variablename= from the start of curve labels.

lty
vector of line types to use for different factor levels. Default is c(1,3,4,5,6,7,...).

lwd
vector of line widths to use for different factor levels. Default is current par setting for lwd.

col
color for curve, default is 1. Specify a vector to assign different colors to different curves. For survplotp, col is a vector of colors corresponding to strata, or a function that will be called to generate such colors.

col.fill
a vector of colors to used in filling confidence bands

adj.subtitle
set to FALSE to suppress plotting subtitle with levels of adjustment factors not plotted. Defaults to TRUE. This argument is ignored for npsurv.

loglog
set to TRUE to plot log(-log Survival) instead of Survival

fun
specifies any function to translate estimates and confidence limits before plotting. If the fit is a multi-state object the default for fun is function(y) 1 - y to draw cumulative incidence curves.

logt
set to TRUE to plot log(t) instead of t on the x-axis

n.risk
set to TRUE to add number of subjects at risk for each curve, using the surv.summary created by cph or using the failure times used in fitting the model if y=TRUE was specified to the fit or if the fit was from npsurv. The numbers are placed at the bottom of the graph unless y.n.risk is given. If the fit is from survest.psm, n.risk does not apply.
angle of rotation for leftmost number of subjects at risk (since this number may run into the second or into the y-axis). Default is 0.

justification for leftmost number at risk. Default is 1 for right justification. Use 0 for left justification, .5 for centered.

multiple of upper y limit - lower y limit for separating lines of text containing number of subjects at risk. Default is .056*(ylim[2]-ylim[1]).

When n.risk=TRUE, the default is to place numbers of patients at risk above the x-axis. You can specify a y-coordinate for the bottom line of the numbers using y.n.risk. Specify y.n.risk='auto' to place the numbers below the x-axis at a distance of 1/3 of the range of ylim.

character size for number of subjects at risk (when n.risk is TRUE)

cex for x-axis label

cex for y-axis label

set to TRUE to plot a grid of dots. Will be plotted at every time.inc (see cph) and at survival increments of .1 (if d>.4), .05 (if .2 < d <= .4), or .025 (if d <= .2), where d is the range of survival displayed.

size of dots in inches

defaults to NULL (not drawing grid lines). Set to TRUE to plot gray(.8) grid lines, or specify any color.

set to TRUE to print survival curve coordinates used in the plots

set to TRUE to add number of events and exponential distribution hazard rate estimates in curve labels. For competing risk data the number of events is for the cause of interest, and the hazard rate is the number of events divided by the sum of all failure and censoring times.

a numeric vector of times at which to compute cumulative incidence probability estimates to add to curve labels

an integer vector of length two specifying the order of groups when computing survival differences. The default of 1:2 indicates that the second group is subtracted from the first. Specify order=2:1 to instead subtract the first from the second. A subtitle indicates what was done.

a function to convert the output of summary.survfitms to pick off the data needed for a single state

survplot will not work for Cox models with time-dependent covariables. Use survest or survfit for that purpose.

There is a set a system option mgp.axis.labels to allow x and y-axes to have differing mgp graphical parameters (see par). This is important when labels for y-axis tick marks are to be written horizontally (par(1as=1)), as a larger gap between the labels and the tick marks are needed. You can set the axis-specific 2nd component of mgp using mgp.axis.labels(c(xvalue,yvalue)).
**Value**

list with components adjust (text string specifying adjustment levels) and curve.labels (vector of text strings corresponding to levels of factor used to distinguish curves). For npsurv, the returned value is the vector of strata labels, or NULL if there are no strata.

**Side Effects**

plots. If par()$mar[4] < 4, issues par(mar=) to increment mar[4] by 2 if n.risk=TRUE and add=FALSE. The user may want to reset par(mar) in this case to not leave such a wide right margin for plots. You usually would issue par(mar=c(5,4,4,2)+.1).

**val.prob**  

**Validate Predicted Probabilities**

**Description**

The `val.prob` function is useful for validating predicted probabilities against binary events. Given a set of predicted probabilities `p` or predicted log odds `logit`, and a vector of binary outcomes `y` that were not used in developing the predictions `p` or `logit`, `val.prob` computes the following indexes and statistics: Somers’ $D_{xy}$ rank correlation between `p` and `y`, $[2(C − .5), C=ROC$ area], Nagelkerke-Cox-Snell-Maddala-Magee R-squared index, Discrimination index $D$ [Logistic model $L.R. \chi^2 - 1)/n$], $L.R. \chi^2$, its $P$-value, Unreliability index $U$, $\chi^2$ with 2 d.f. for testing unreliability (H0: intercept=0, slope=1), its $P$-value, the quality index $Q$, Brier score (average squared difference in $p$ and $y$), Intercept, and Slope, $E_{max}$=maximum absolute difference in predicted and loess-calibrated probabilities, $E_{avg}$, the average in same, $E_{90}$, the 0.9 quantile of same, the Spiegelhalter $Z$-test for calibration accuracy, and its two-tailed $P$-value. If `pl=TRUE`, plots fitted logistic calibration curve and optionally a smooth nonparametric fit using `lowess(p,y,iter=0)` and grouped proportions vs. mean predicted probability in group. If the predicted probabilities or logits are constant, the statistics are returned and no plot is made. $E_{avg}$, $E_{max}$, $E_{90}$ were from linear logistic calibration before `rms 4.5-1`.

When `group` is present, different statistics are computed, different graphs are made, and the object returned by `val.prob` is different. `group` specifies a stratification variable. Validations are done separately by levels of group and overall. A `print` method prints summary statistics and several quantiles of predicted probabilities, and a `plot` method plots calibration curves with summary statistics superimposed, along with selected quantiles of the predicted probabilities (shown as tick marks on calibration curves). Only the `lowess` calibrated probability curve is estimated. The statistics computed are the average predicted probability, the observed proportion of events, a 1 d.f. chi-square statistic for testing for overall mis-calibration (i.e., a test of the observed vs. the overall average predicted probability of the event) ($ChiSq$), and a 2 d.f. chi-square statistic for testing simultaneously that the intercept of a linear logistic calibration curve is zero and the slope is one ($ChiSq2$), average absolute calibration error (average absolute difference between the `lowess`-estimated calibration curve and the line of identity, labeled $E_{avg}$), $E_{avg}$ divided by the difference between the 0.95 and 0.05 quantiles of predictive probabilities ($E_{avg}/P_{90}$), a “median odds ratio”, i.e., the anti-log of the median
absolute difference between predicted and calibrated predicted log odds of the event (Med OR), the C-index (ROC area), the Brier quadratic error score (B), a chi-square test of goodness of fit based on the Brier score (B ChiSq), and the Brier score computed on calibrated rather than raw predicted probabilities (B cal). The first chi-square test is a test of overall calibration accuracy ("calibration in the large"), and the second will also detect errors such as slope shrinkage caused by overfitting or regression to the mean. See Cox (1970) for both of these score tests. The goodness of fit test based on the (uncalibrated) Brier score is due to Hilden, Habbema, and Bjørregård (1978) and is discussed in Spiegelhalter (1986). When group is present you can also specify sampling weights (usually frequencies), to obtained weighted calibration curves.

To get the behavior that results from a grouping variable being present without having a grouping variable, use group=TRUE. In the plot method, calibration curves are drawn and labeled by default where they are maximally separated using the labcurve function. The following parameters do not apply when group is present: pl, smooth, logistic.cal, m, g, cuts, emax.lim, legendloc, riskdist, mkh, connect.group, connect.smooth. The following parameters apply to the plot method but not to val.prob: xlab, ylab, lim, statloc, cex.

Usage

val.prob(p, y, logit, group, weights=rep(1,length(y)), normwt=FALSE, pl=TRUE, smooth=TRUE, logistic.cal=TRUE, xlab="Predicted Probability", ylab="Actual Probability", lim=c(0,1), m, g, cuts, emax.lim=c(0,1), legendloc=lim[1] + c(0.55 * diff(lim), 0.27 * diff(lim)), statloc=c(0,0.99), riskdist=c("predicted", "calibrated"), cex=.7, mkh=.02, connect.group=FALSE, connect.smooth=TRUE, g.group=4, evaluate=100, nmin=0)

## S3 method for class 'val.prob'
print(x, ...)

## S3 method for class 'val.prob'
plot(x, xlab="Predicted Probability", ylab="Actual Probability", lim=c(0,1), statloc=lim, stats=1:12, cex=.5, lwd.overall=4, quantiles=c(.05,.95), flag, ...)

Arguments

p predicted probability
y vector of binary outcomes
logit predicted log odds of outcome. Specify either p or logit.
group a grouping variable. If numeric this variable is grouped into g.group quantile groups (default is quartiles). Set group=TRUE to use the group algorithm but with a single stratum for val.prob.
weights an optional numeric vector of per-observation weights (usually frequencies), used only if group is given.
normwt TRUE to make weights sum to the number of non-missing observations.
pl TRUE to plot calibration curves and optionally statistics
smooth plot smooth fit to (p,y) using lowess(p,y,iter=0)
logistic.cal plot logistic calibration fit to (p,y)
xlab x-axis label, default is "Predicted Probability" for val.prob.
ylab y-axis label, default is "Actual Probability" for val.prob.
lm limits for both x and y axes
m If grouped proportions are desired, average no. observations per group
g If grouped proportions are desired, number of quantile groups
cuts If grouped proportions are desired, actual cut points for constructing intervals, e.g. c(0,.1,.8,.9,1) or seq(0,1,by=.2)
emax.lim Vector containing lowest and highest predicted probability over which to compute Emax.
legendloc If pl=TRUE, list with components x, y or vector c(x,y) for upper left corner of legend for curves and points. Default is c(.55, .27) scaled to lim. Use locator(1) to use the mouse, FALSE to suppress legend.
statloc Dxy, C, R^2, D, U, Q, Brier score, Intercept, Slope, and E_{max} will be added to plot, using statloc as the upper left corner of a box (default is c(0,.9)). You can specify a list or a vector. Use locator(1) for the mouse, FALSE to suppress statistics. This is plotted after the curve legends.
riskdist Use "calibrated" to plot the relative frequency distribution of calibrated probabilities after dividing into 101 bins from lim[1] to lim[2]. Set to "predicted" (the default as of rms 4.5-1) to use raw assigned risk, FALSE to omit risk distribution. Values are scaled so that highest bar is 0.15*(lim[2]-lim[1]).
cex Character size for legend or for table of statistics when group is given
mkh Size of symbols for legend. Default is 0.02 (see par()).
connect.group Defaults to FALSE to only represent group fractions as triangles. Set to TRUE to also connect with a solid line.
connect.smooth Defaults to TRUE to draw smoothed estimates using a dashed line. Set to FALSE to instead use dots at individual estimates.
g.group number of quantile groups to use when group is given and variable is numeric.
evaluate number of points at which to store the lowess-calibration curve. Default is 100. If there are more than evaluate unique predicted probabilities, evaluate equally-spaced quantiles of the unique predicted probabilities, with linearly interpolated calibrated values, are retained for plotting (and stored in the object returned by val.prob.
nmin applies when group is given. When nmin > 0, val.prob will not store coordinates of smoothed calibration curves in the outer tails, where there are fewer than nmin raw observations represented in those tails. If for example nmin=50, the plot function will only plot the estimated calibration curve from a to b, where there are 50 subjects with predicted probabilities < a and > b. nmin is ignored when computing accuracy statistics.
val.prob

x  result of val.prob (with group in effect)

...  optional arguments for labcurve (through plot). Commonly used options are
col (vector of colors for the strata plus overall) and lty. Ignored for print.

stats  vector of column numbers of statistical indexes to write on plot

lwd.overall  line width for plotting the overall calibration curve

quantiles  a vector listing which quantiles should be indicated on each calibration curve
using tick marks. The values in quantiles can be any number of values from
the following: .01, .025, .05, .1, .25, .5, .75, .9, .95, .975, .99. By default the
0.05 and 0.95 quantiles are indicated.

flag  a function of the matrix of statistics (rows representing groups) returning a vec-
tor of character strings (one value for each group, including "Overall"). plot.val.prob
will print this vector of character values to the left of the statistics. The flag
function can refer to columns of the matrix used as input to the function by their
names given in the description above. The default function returns "+" if either
ChiSq2 or B ChiSq is significant at the 0.01 level and " " otherwise.

Details

The 2 d.f. \( \chi^2 \) test and Med OR exclude predicted or calibrated predicted probabilities \( \leq 0 \) to zero or
\( \geq 1 \), adjusting the sample size as needed.

Value

val.prob without group returns a vector with the following named elements: Dxy, R2, D:Chi-sq,
D:p, U, U:Chi-sq, U:p, Q, Brier, Intercept, Slope, S:z, S:p, Emax. When group is present
val.prob returns an object of class val.prob containing a list with summary statistics and calibration
curves for all the strata plus "Overall".

val.surv

Validate Predicted Probabilities Against Observed Survival Times

Description

The `val.surv` function is useful for validating predicted survival probabilities against right-censored failure times. If `u` is specified, the hazard regression function `hare` in the `polspine` package is used to relate predicted survival probability at time `u` to observed survival times (and censoring indicators) to estimate the actual survival probability at time `u` as a function of the estimated survival probability at that time, `est.surv`. If `est.surv` is not given, `fit` must be specified and the `survest` function is used to obtain the predicted values (using `newdata` if it is given, or using the stored linear predictor values if not). `hare` is given the sole predictor `fun(est.surv)` where `fun` is given by the user or is inferred from `fit`. `fun` is the function of predicted survival probabilities that one expects to create a linear relationship with the linear predictors.

`hare` uses an adaptive procedure to find a linear spline of `fun(est.surv)` in a model where the log hazard is a linear spline in time `t`, and cross-products between the two splines are allowed so as to not assume proportional hazards. Thus `hare` assumes that the covariate and time functions are smooth but not much else, if the number of events in the dataset is large enough for obtaining a reliable flexible fit. There are special `print` and `plot` methods when `u` is given. In this case, `val.surv` returns an object of class "val.survh", otherwise it returns an object of class "val.surv".

If `u` is not specified, `val.surv` uses Cox-Snell (1968) residuals on the cumulative probability scale to check on the calibration of a survival model against right-censored failure time data. If the predicted survival probability at time `t` for a subject having predictors `X` is `S(t|X)`, this method is based on the fact that the predicted probability of failure before time `t`, `1 - S(t|X)`, when evaluated at the subject’s actual survival time `T`, has a uniform (0,1) distribution. The quantity `1 - S(T|X)` is right-censored when `T` is. By getting one minus the Kaplan-Meier estimate of the distribution of `1 - S(T|X)` and plotting against the 45 degree line we can check for calibration accuracy. A more stringent assessment can be obtained by stratifying this analysis by an important predictor variable. The theoretical uniform distribution is only an approximation when the survival probabilities are estimates and not population values.

When `censor` is specified to `val.surv`, a different validation is done that is more stringent but that only uses the uncensored failure times. This method is used for type I censoring when the theoretical censoring times are known for subjects having uncensored failure times. Let `T`, `C`, and `F` denote respectively the failure time, censoring time, and cumulative failure time distribution `(1 - S)`. The expected value of `F(T|X)` is 0.5 when `T` represents the subject’s actual failure time. The expected value for an uncensored time is the expected value of `F(T|T \leq C, X) = 0.5F(C|X)`. A smooth plot of `F(T|X) - 0.5F(C|X)` for uncensored `T` should be a flat line through `y = 0` if the model is well calibrated. A smooth plot of `2F(T|X) / F(C|X)` for uncensored `T` should be a flat line through `y = 1`. The smooth plot is obtained by smoothing the (linear predictor, difference or ratio) pairs.
Usage

val.surv(fit, newdata, S, est.surv, censor,
        u, fun, lim, evaluate=100, pred, maxdim=5, ...)

## S3 method for class 'val.surv'
print(x, ...)

## S3 method for class 'val.surv'
plot(x, lim, xlab, ylab,
     riskdist=TRUE, add=FALSE,
     scat1d.opts=list(nhistSpike=200), ...)

## S3 method for class 'val.surv'
plot(x, group, g.group=4,
     what=c('difference','ratio'),
     type=c('l','b','p'),
     xlab, ylab, xlim, ylim, datadensity=TRUE, ...)

Arguments

fit a fit object created by cph or psm
newdata a data frame for which val.surv should obtain predicted survival probabilities. If omitted, survival estimates are made for all of the subjects used in fit.
S an Surv object
est.surv a vector of estimated survival probabilities corresponding to times in the first column of S.
censor a vector of censoring times. Only the censoring times for uncensored observations are used.
u a single numeric follow-up time
fun a function that transforms survival probabilities into the scale of the linear predictor. If fit is given, and represents either a Cox, Weibull, or exponential fit, fun is automatically set to log(-log(p)).
lim a 2-vector specifying limits of predicted survival probabilities for obtaining estimated actual probabilities at time u. Default for val.surv is the limits for predictions from datadist, which for large n is the 10th smallest and 10th largest predicted survival probability. For plot.val.surv, the default for lim is the range of the combination of predicted probabilities and calibrated actual probabilities. lim is used for both axes of the calibration plot.
evaluate the number of evenly spaced points over the range of predicted probabilities. This defines the points at which calibrated predictions are obtained for plotting.
pred a vector of points at which to evaluate predicted probabilities, overriding lim
maxdim see hare
x result of val.surv
xlab x-axis label. For plot.surv, defaults for xlab and ylab come from u and the units of measurement for the raw survival times.
val.surv

ylab  y-axis label

riskdist  set to FALSE to not call scat1d to draw the distribution of predicted (uncalibrated) probabilities

add  set to TRUE if adding to an existing plot

scat1d.opts  a list of options to pass to scat1d. By default, the option nhistSpike=200 is passed so that a spike histogram is used if the sample size exceeds 200.

...  When u is given to val.surv, ... represents optional arguments to hare. It can represent arguments to pass to plot or lines for plot.val.surv. Otherwise, ... contains optional arguments for plsmo or plot. For print.val.survh, ... is ignored.

group  a grouping variable. If numeric this variable is grouped into g.group quantile groups (default is quartiles). group, g.group, what, and type apply when u is not given.

g.group  number of quantile groups to use when group is given and variable is numeric.

what  the quantity to plot when censor was in effect. The default is to show the difference between cumulative probabilities and their expectation given the censoring time. Set what="ratio" to show the ratio instead.

type  Set to the default ("l") to plot the trend line only, "b" to plot both individual subjects ratios and trend lines, or "p" to plot only points.

xlim  ylim  axis limits for plot.val.surv when the censor variable was used.

datadensity  By default, plot.val.surv will show the data density on each curve that is created as a result of censor being present. Set datadensity=FALSE to suppress these tick marks drawn by scat1d.

Value

a list of class "val.surv" or "val.survh"

validate

Resampling Validation of a Fitted Model's Indexes of Fit

Description

The `validate` function when used on an object created by one of the `rms` series does resampling validation of a regression model, with or without backward step-down variable deletion.

Usage

```r
# fit <- fitting.function(formula=response ~ terms, x=TRUE, y=TRUE)
validate(fit, method="boot", B=40,
        bw=FALSE, rule="aic", type="residual", sls=0.05, aics=0,
        force=NULL, estimates=TRUE, pr=FALSE, ...)
```

Arguments

- `fit` a fit derived by e.g. `lrm`, `cph`, `psm`, `ols`. The options `x=TRUE` and `y=TRUE` must have been specified.
- `method` may be "crossvalidation", "boot" (the default), ".632", or "randomization". See `predab.resample` for details. Can abbreviate, e.g. "cross", "b", ".6".
- `B` number of repetitions. For method="crossvalidation", is the number of groups of omitted observations. For `print.validate`, `latex.validate`, and `html.validate`, `B` is an upper limit on the number of resamples for which information is printed about which variables were selected in each model re-fit. Specify zero to suppress printing. Default is to print all re-samples.
- `bw` TRUE to do fast step-down using the `fastbw` function, for both the overall model and for each repetition. `fastbw` keeps parameters together that represent the same factor.
- `rule` Applies if `bw=TRUE"aic" to use Akaike's information criterion as a stopping rule (i.e., a factor is deleted if the $\chi^2$ falls below twice its degrees of freedom), or "p" to use $P$-values.
type: "residual" or "individual" - stopping rule is for individual factors or for the residual $\chi^2$ for all variables deleted

sls: significance level for a factor to be kept in a model, or for judging the residual $\chi^2$.

aics: cutoff on AIC when rule="aic".

force: see fastbw

estimates: see print.fastbw

pr: TRUE to print results of each repetition

...parameters for each specific validate function, and parameters to pass to predab.resample (note especially the group, cluster, amd subset parameters). For latex, optional arguments to latex.default. Ignored for html.validate.

For psm, you can pass the maxiter parameter here (passed to survreg.control, default is 15 iterations) as well as a tol parameter for judging matrix singularity in solvet (default is 1e-12) and a rel.tolerance parameter that is passed to survreg.control (default is 1e-5).

For print.validate ...is ignored.

x,object: an object produced by one of the validate functions
digits: number of decimal places to print

file: file to write LaTeX output. Default is standard output.

append: set to TRUE to append LaTeX output to an existing file
title, caption, table.env, extracolsize: see latex.default. If table.env is FALSE and caption is given, the character string contained in caption will be placed before the table, centered.

size: size of LaTeX output. Default is 'normalsize'. Must be a defined LaTeX size when prepended by double slash.

Details

It provides bias-corrected indexes that are specific to each type of model. For validate.cph and validate.psm, see validate.lrm, which is similar.

For validate.cph and validate.psm, there is an extra argument dxy, which if TRUE causes the dxy.cens function to be invoked to compute the Somers' $D_{xy}$ rank correlation to be computed at each resample. The values corresponding to the row $D_{xy}$ are equal to $2 \times (C - 0.5)$ where C is the C-index or concordance probability.

For validate.cph with dxy=TRUE, you must specify an argument u if the model is stratified, since survival curves can then cross and $X\beta$ is not 1-1 with predicted survival.

There is also validate method for tree, which only does cross-validation and which has a different list of arguments.

Value

a matrix with rows corresponding to the statistical indexes and columns for columns for the original index, resample estimates, indexes applied to the whole or omitted sample using the model derived from the resample, average optimism, corrected index, and number of successful re-samples.
Side Effects

prints a summary, and optionally statistics for each re-fit

validate.ols, validate.cph, validate.lrm, validate.rpart, predab.resample, fastbw, rms, rms.trans, calibrate, dxy.cens, survConcordance

Examples

# See examples for validate.cph, validate.lrm, validate.ols
# Example of validating a parametric survival model:

n <- 1000
set.seed(731)
age <- 50 + 12*rnorm(n)
label(age) <- "Age"
sex <- factor(sample(c("Male", "Female"), n, TRUE))
cens <- 15*runif(n)
h <- .02*exp(.04*(age-50)+.8*(sex=='Female'))
dt <- -log(runif(n))/h
e <- ifelse(dt <= cens,1,0)
dt <- pmin(dt, cens)
units(dt) <- "Year"
S <- Surv(dt,e)

f <- psm(S ~ age*sex, x=TRUE, y=TRUE) # Weibull model
# Validate full model fit
validate(f, B=10) # usually B=150

# Validate stepwise model with typical (not so good) stopping rule
# bw=TRUE does not preserve hierarchy of terms at present
validate(f, B=10, bw=TRUE, rule="p", sls=.1, type="individual")
**Description**

This is the version of the `validate` function specific to models fitted with `cph` or `psm`. Also included is a small function `dxy.cens` that retrieves $D_{xy}$ and its standard error from the `survConcordance.fit` function. This allows for incredibly fast computation of $D_{xy}$ or the c-index even for hundreds of thousands of observations. `dxy.cens` negates $D_{xy}$ if log relative hazard is being predicted. If `y` is a left-censored `Surv` object, times are negated and a right-censored object is created, then $D_{xy}$ is negated.

**Usage**

```r
# fit <- cph(formula=Surv(ftime,event) ~ terms, x=TRUE, y=TRUE, \dots)

## S3 method for class 'cph'
validate(fit, method="boot", B=40, bw=FALSE, rule="aic", 
         type="residual", sls=.05, aics=0, force=NULL, estimates=TRUE, 
         pr=FALSE, dxy=TRUE, u, tol=1e-9, \dots)

## S3 method for class 'psm'
validate(fit, method="boot", B=40, 
         bw=FALSE, rule="aic", type="residual", sls=.05, aics=0, 
         force=NULL, estimates=TRUE, pr=FALSE, 
         dxy=TRUE, tol=1e-12, rel.tolerance=1e-5, maxiter=15, \dots)

dxy.cens(x, y, type=c('time','hazard'))
```

**Arguments**

- `fit`: a fit derived `cph`. The options `x=TRUE` and `y=TRUE` must have been specified. If the model contains any stratification factors and `dxy=TRUE`, the options `surv=TRUE` and `time.inc=u` must also have been given, where `u` is the same value of `u` given to `validate`.
- `method`: see `validate`.
- `B`: number of repetitions. For method="crossvalidation", is the number of groups of omitted observations.
- `rel.tolerance, maxiter, bw`: TRUE to do fast step-down using the `fastbw` function, for both the overall model and for each repetition. `fastbw` keeps parameters together that represent the same factor.
- `rule`: Applies if `bw=TRUE`. "aic" to use Akaike’s information criterion as a stopping rule (i.e., a factor is deleted if the $\chi^2$ falls below twice its degrees of freedom), or "p" to use $P$-values.
- `type`: "residual" or "individual" - stopping rule is for individual factors or for the residual $\chi^2$ for all variables deleted. For `dxy.cens`, specify `type="hazard"` if `x` is on the hazard or cumulative hazard (or their logs) scale, causing negation of the correlation index.
- `sls`: significance level for a factor to be kept in a model, or for judging the residual $\chi^2$.
- `aics`: cutoff on AIC when rule="aic".
force  see fastbw
estimates see print.fastbw
pr TRUE to print results of each repetition
tol,... see validate or predab.resample
dxy set to TRUE to validate Somers’ $D_{xy}$ using dxy.cens, which is fast until $n > 500,000$. Uses the survival package’s survConcordance.fit service function for survConcordance.
u must be specified if the model has any stratification factors and dxy=TRUE. In that case, strata are not included in $X\beta$ and the survival curves may cross. Predictions at time $t=u$ are correlated with observed survival times. Does not apply to validate.psm.
x a numeric vector
y a Surv object that may be uncensored or right-censored

Details

Statistics validated include the Nagelkerke $R^2$, $D_{xy}$, slope shrinkage, the discrimination index $D$ [(model L.R. $\chi^2$ - 1)/L], the unreliability index $U = \text{(difference in -2 log likelihood between uncalibrated } X\beta \text{ and } X\beta \text{ with overall slope calibrated to test sample)} / L$, and the overall quality index $Q = D - U$. $g$ is the $g$-index on the log relative hazard (linear predictor) scale. L is -2 log likelihood with beta=0. The "corrected" slope can be thought of as shrinkage factor that takes into account overfitting. See predab.resample for the list of resampling methods.

Value

matrix with rows corresponding to $D_{xy}$, Slope, $D$, $U$, and $Q$, and columns for the original index, resample estimates, indexes applied to whole or omitted sample using model derived from resample, average optimism, corrected index, and number of successful resamples.

The values corresponding to the row $D_{xy}$ are equal to $2 \times (C - 0.5)$ where $C$ is the C-index or concordance probability. If the user is correlating the linear predictor (predicted log hazard) with survival time, $D_{xy}$ is automatically negated.

Side Effects

prints a summary, and optionally statistics for each re-fit (if pr=TRUE)

# one to choose a single time at which to predict S(t|X)
f <- cph(S ~ rcs(age)*strat(sex),
            x=TRUE, y=TRUE, surv=TRUE, time.inc=2)
validate(f, u=2, B=10) # normally B=150
# Note u=time.inc
```

validate.lrm  
Resampling Validation of a Logistic or Ordinal Regression Model

Description

The `validate` function when used on an object created by `lrm` or `orm` does resampling validation of a logistic regression model, with or without backward step-down variable deletion. It provides bias-corrected Somers' $D_{xy}$ rank correlation, R-squared index, the intercept and slope of an overall logistic calibration equation, the maximum absolute difference in predicted and calibrated probabilities $E_{max}$, the discrimination index $D$ (model L.R. $(\chi^2 - 1)/n$), the unreliability index $U$ = difference in -2 log likelihood between un-calibrated $X\beta$ and $X\beta$ with overall intercept and slope calibrated to test sample / n, the overall quality index (logarithmic probability score) $Q = D - U$, and the Brier or quadratic probability score, $B$ (the last 3 are not computed for ordinal models), the $g$-index, and gp, the $g$-index on the probability scale. The corrected slope can be thought of as shrinkage factor that takes into account overfitting. For `orm` fits, a subset of the above indexes is provided, Spearman’s $\rho$ is substituted for $D_{xy}$, and a new index is reported: $pdm$, the mean absolute difference between 0.5 and the predicted probability that $Y \geq$ the marginal median of $Y$.

Usage

```r
# fit <- lrm(formula=response ~ terms, x=TRUE, y=TRUE) or orm
## S3 method for class 'lrm'
```
validate.lrm

validate(fit, method="boot", B=40,
        bw=FALSE, rule="aic", type="residual", sls=0.05, aics=0,
        force=NULL, estimates=TRUE,
        pr=FALSE, kint, Dxy.method=if(k==1) 'somers2' else 'lrm',
        emax.lim=c(0,1), ...)

## S3 method for class 'orm'
validate(fit, method="boot", B=40, bw=FALSE, rule="aic",
        type="residual", sls=.05, aics=0, force=NULL, estimates=TRUE,
        pr=FALSE, ...)

Arguments

fit a fit derived by lrm or orm. The options x=TRUE and y=TRUE must have been
    specified.
method, B, bw, rule, type, sls, aics, force, estimates, pr
    see validate and predab.resample
kint In the case of an ordinal model, specify which intercept to validate. Default is
    the middle intercept. For validate.orm, intercept-specific quantities are not
    validated so this does not matter.
Dxy.method "lrm" to use lrm computation of $D_{xy}$ correlation, which rounds predicted
    probabilities to nearest .002. Use Dxy.method="somers2" (the default) to in-
    stead use the more accurate but slower somers2 function. This will matter most
    when the model is extremely predictive. The default is "lrm" for ordinal mod-
    els, since somers2 only handles binary response variables.
emax.lim range of predicted probabilities over which to compute the maximum error. De-
    fault is entire range.
... other arguments to pass to lrm.fit (now only maxit and tol are allowed) and
to predab.resample (note especially the group, cluster, and subset param-
eters)

Details

If the original fit was created using penalized maximum likelihood estimation, the same penalty.matrix
used with the original fit are used during validation.

Value

a matrix with rows corresponding to $D_{xy}$, $R^2$, Intercept, Slope, $E_{max}$, $D$, $U$, $Q$, $B$, $g$, $gp$, and
    columns for the original index, resample estimates, indexes applied to the whole or omitted sample
using the model derived from the resample, average optimism, corrected index, and number of
successful re-samples. For validate.orm not all columns are provided, Spearman’s rho is returned
instead of $D_{xy}$, and $pdm$ is reported.

Side Effects

prints a summary, and optionally statistics for each re-fit

#see predab.resample for cluster and subset

## End(Not run)

validate.ols

Validation of an Ordinary Linear Model

Description

The validate function when used on an object created by ols does resampling validation of a multiple linear regression model, with or without backward step-down variable deletion. Uses resampling to estimate the optimism in various measures of predictive accuracy which include $R^2$, $MSE$ (mean squared error with a denominator of $n$), the $g$-index, and the intercept and slope of an overall calibration $a + b\hat{y}$. The "corrected" slope can be thought of as shrinkage factor that takes into account overfitting. validate.ols can also be used when a model for a continuous response is going to be applied to a binary response. A Somers’ $D_{xy}$ for this case is computed for each resample by dichotomizing $y$. This can be used to obtain an ordinary receiver operating characteristic curve area using the formula $0.5(D_{xy} + 1)$. The Nagelkerke-Maddala $R^2$ index for the dichotomized $y$ is also given. See predab.resample for the list of resampling methods.

The LaTeX needspace package must be in effect to use the \texttt{latex} method.

Usage

# fit <- fitting.function(formula=response ~ terms, x=TRUE, y=TRUE)
## S3 method for class 'ols'
validate(fit, method="boot", B=40,
        bw=FALSE, rule="aic", type="residual", sls=0.05, aics=0,
        force=NULL, estimates=TRUE, pr=FALSE, u=NULL, rel=">",
        tolerance=1e-7, ...)

Arguments

fit            a fit derived by ols. The options x=TRUE and y=TRUE must have been specified. See validate for a description of arguments method - pr.
method,B,bw,rule,type,sls,aics,force,estimates,pr 
see validate and predab.resample and fastbw
u             If specified, $y$ is also dichotomized at the cutoff $u$ for the purpose of getting a bias-corrected estimate of $D_{xy}$.
rel            relationship for dichotomizing predicted $y$. Defaults to ">" to use $y>u$. rel can also be "<", "="." and "<=".
tolerance      tolerance for singularity; passed to \texttt{lm.fit.qr}.
...            other arguments to pass to predab.resample, such as group, cluster, and subset
validate.rpart

Value

matrix with rows corresponding to R-square, MSE, g, intercept, slope, and optionally $D_{xy}$ and $R^2$, and columns for the original index, resample estimates, indexes applied to whole or omitted sample using model derived from resample, average optimism, corrected index, and number of successful resamples.

Side Effects

prints a summary, and optionally statistics for each re-fit

Author(s)

Frank Harrell
Department of Biostatistics, Vanderbilt University
fh@fharrell.com

See Also

ols, predab.resample, fastbw, rms, rms.trans, calibrate, gIndex

Examples

set.seed(1)
x1 <- runif(200)x2 <- sample(0:3, 200, TRUE)x3 <- rnorm(200)distance <- (x1 + x2/3 + rnorm(200))^2

f <- ols(sqrt(distance) ~ rcs(x1,4) + scored(x2) + x3, x=TRUE, y=TRUE)

#Validate full model fit (from all observations) but for x1 < .75 validate(f, B=20, subset=x1 < .75)  # normally B=300

#Validate stepwise model with typical (not so good) stopping rule validate(f, B=20, bw=TRUE, rule="p", sls=.1, type="individual")

validate.rpart

Dxy and Mean Squared Error by Cross-validating a Tree Sequence

Description

Uses xval-fold cross-validation of a sequence of trees to derive estimates of the mean squared error and Somers’ Dxy rank correlation between predicted and observed responses. In the case of a binary response variable, the mean squared error is the Brier accuracy score. For survival trees, Dxy is negated so that larger is better. There are print and plot methods for objects created by validate.rpart.
validate.rpart

Usage

# f <- rpart(formula=y ~ x1 + x2 + \dots) # or rpart
## S3 method for class 'rpart'
validate(fit, method, B, bw, rule, type, sls, aics,
         force, estimates, pr=TRUE,
         k, rand, xval=10, FUN, ...)
## S3 method for class 'validate.rpart'
print(x, ...)
## S3 method for class 'validate.rpart'
plot(x, what=c("mse","dxy"), legendloc=locator, ...)

Arguments

fit an object created by rpart. You must have specified the model=TRUE argument to rpart.
method,B,bw,rule,type,sls,aics,force,estimates
are there only for consistency with the generic validate function; these are ignored
x the result of validate.rpart
k a sequence of cost/complexity values. By default these are obtained from calling
FUN with no optional arguments or from the rpart cptable object in the original
fit object. You may also specify a scalar or vector.
rand a random sample (usually omitted)
xval number of splits
FUN the name of a function which produces a sequence of trees, such as prune.
... additional arguments to FUN (ignored by print, plot).
pr set to FALSE to prevent intermediate results for each k to be printed
what a vector of things to plot. By default, 2 plots will be done, one for mse and one
for Dxy.
legendloc a function that is evaluated with a single argument equal to 1 to generate a list
with components x, y specifying coordinates of the upper left corner of a legend,
or a 2-vector. For the latter, legendloc specifies the relative fraction of the
plot at which to center the legend.

Value

a list of class "validate.rpart" with components named k, size, dxy.app, dxy.val, mse.app,
mse.val, binary, xval. size is the number of nodes. dxy refers to Somers' D, mse refers to mean
squared error of prediction, app means apparent accuracy on training samples, val means validated
accuracy on test samples. binary is a logical variable indicating whether or not the response variable
was binary (a logical or 0/1 variable is binary). size will not be present if the user specifies k.

Side Effects

prints if pr=TRUE
validate.Rq

Validation of a Quantile Regression Model

Description

The validate function when used on an object created by Rq does resampling validation of a quantile regression model, with or without backward step-down variable deletion. Uses resampling to estimate the optimism in various measures of predictive accuracy which include mean absolute prediction error (MAD), Spearman rho, the g-index, and the intercept and slope of an overall calibration \( a + b\hat{y} \). The "corrected" slope can be thought of as shrinkage factor that takes into account overfitting. validate.Rq can also be used when a model for a continuous response is going to be applied to a binary response. A Somers' \( D_{xy} \) for this case is computed for each resample by dichotomizing y. This can be used to obtain an ordinary receiver operating characteristic curve area using the formula \( 0.5(D_{xy} + 1) \). See predab.resample for the list of resampling methods.

The \LaTeX{} needspace package must be in effect to use the latex method.
validate.Rq

Usage

# fit <- fitting.function(formula=response ~ terms, x=TRUE, y=TRUE)
## S3 method for class 'Rq'
validate(fit, method="boot", B=40,
bw=FALSE, rule="aic", type="residual", sls=0.05, aics=0,
force=NULL, estimates=TRUE, pr=FALSE, u=NULL, rel=">",
tolerance=1e-7, ...)

Arguments

fit a fit derived by Rq. The options x=TRUE and y=TRUE must have been specified. See validate for a description of arguments method - pr.
method,B,bw,rule,type,sls,aics,force,estimates,pr
see validate and predab.resample and fastbw
u If specified, y is also dichotomized at the cutoff u for the purpose of getting a bias-corrected estimate of $D_{xy}$.
rel relationship for dichotomizing predicted y. Defaults to ">" to use y>u. rel can also be "<", "=" and "<=".
tolerance ignored
... other arguments to pass to predab.resample, such as group, cluster, and subset

Value

matrix with rows corresponding to various indexes, and optionally $D_{xy}$, and columns for the original index, resample estimates, indexes applied to whole or omitted sample using model derived from resample, average optimism, corrected index, and number of successful resamples.

Side Effects

prints a summary, and optionally statistics for each re-fit

Author(s)

Frank Harrell
Department of Biostatistics, Vanderbilt University
fh@fharrell.com

See Also

Rq, predab.resample, fastbw, rms, rms.trans, gIndex

Examples

set.seed(1)
x1 <- runif(200)
x2 <- sample(0:3, 200, TRUE)
x3 <- rnorm(200)
distance <- (x1 + x2/3 + rnorm(200))^2
f <- Rq(sqrt(distance) ~ rcs(x1,4) + scored(x2) + x3, x=TRUE, y=TRUE)

# Validate full model fit (from all observations) but for x1 < .75
validate(f, B=20, subset=x1 < .75)  # normally B=300

# Validate stepwise model with typical (not so good) stopping rule
validate(f, B=20, bw=TRUE, rule="p", sls=.1, type="individual")

---

**vif**

*Variance Inflation Factors*

---

**Description**

Computes variance inflation factors from the covariance matrix of parameter estimates, using the method of Davis et al. (1986), which is based on the correlation matrix from the information matrix.

**Usage**

vif(fit)

**Arguments**

fit  
an object created by `lrm`, `ols`, `psm`, `cph`, `Rq`, `Glm`, `glm`

**Value**

vector of vifs

**Author(s)**

Frank Harrell  
Department of Biostatistics  
Vanderbilt University  
fh@fharrell.com

**References**

**See Also**

`rmsMisc` (for `num.intercepts`)
Examples

```r
set.seed(1)
x1 <- rnorm(100)
x2 <- x1+.1*rnorm(100)
y <- sample(0:1, 100, TRUE)
f <- lrm(y ~ x1 + x2)
vif(f)
```

---

**which.influence**  
*Which Observations are Influential*

**Description**

Creates a list with a component for each factor in the model. The names of the components are the factor names. Each component contains the observation identifiers of all observations that are "overly influential" with respect to that factor, meaning that $|dfbeta_i| > u$ for at least one $\beta_i$ associated with that factor, for a given cutoff. The default cutoff is .2. The fit must come from a function that has `resid(fit, type="dfbetas")` defined.

`show.influence`, written by Jens Oehlschlaegel-Akiyoshi, applies the result of `which.influence` to a data frame, usually the one used to fit the model, to report the results.

**Usage**

```r
which.influence(fit, cutoff=.2)

show.influence(object, dframe, report=NULL, sig=NULL, id=NULL)
```

**Arguments**

- `fit`  
  - fit object
- `object`  
  - the result of `which.influence`
- `dframe`  
  - data frame containing observations pertinent to the model fit
- `cutoff`  
  - cutoff value
- `report`  
  - other columns of the data frame to report besides those corresponding to predictors that are influential for some observations
- `sig`  
  - runs results through `signif` with `sig` digits if `sig` is given
- `id`  
  - a character vector that labels rows of `dframe` if `row.names` were not used

**Value**

`show.influence` returns a marked dataframe with the first column being a count of influence values.
