Package ‘rwa’

October 14, 2022

Type Package
Title Perform a Relative Weights Analysis
Version 0.0.3
Author Martin Chan <martinchan53@gmail.com>
Maintainer Martin Chan <martinchan53@gmail.com>
Description Perform a Relative Weights Analysis (RWA) (a.k.a. Key Drivers Analysis) as per the method described in Tonidandel & LeBreton (2015) <DOI:10.1007/s10869-014-9351-z>, with its original roots in Johnson (2000) <DOI:10.1207/S15327906MBR3501_1>. In essence, RWA decomposes the total variance predicted in a regression model into weights that accurately reflect the proportional contribution of the predictor variables, which addresses the issue of multicollinearity. In typical scenarios, RWA returns similar results to Shapley regression, but with a significant advantage on computational performance.

R topics documented:

plot_rwa ................................................................. 2
remove_all_na_cols .............................................. 2
rwa ................................................................. 3
remove_all_na_cols

Description
Pass a data frame and returns a version where all columns made up of entirely missing values are removed.

Usage
remove_all_na_cols(df)

Arguments
df Data frame to be passed through.

Details
This is used within rwa().

plot_rwa
Plot the rescaled importance values from the output of rwa()

Description
Pass the output of rwa() and plot a bar chart of the rescaled importance values. Signs are always calculated and taken into account, which is equivalent to setting the applysigns argument to TRUE in rwa().

Usage
plot_rwa(rwa)

Arguments
rwa Direct list output from rwa().

Examples
library(ggplot2)
diamonds %>%
rwa(outcome = "price",
predictors = c("depth","carat", "x", "y", "z"),
applysigns = TRUE) %>%
plot_rwa()
Create a Relative Weights Analysis (RWA)

**Description**

This function creates a Relative Weights Analysis (RWA) and returns a list of outputs. RWA provides a heuristic method for estimating the relative weight of predictor variables in multiple regression, which involves creating a multiple regression with on a set of transformed predictors which are orthogonal to each other but maximally related to the original set of predictors. `rwa()` is optimised for dplyr pipes and shows positive / negative signs for weights.

**Usage**

```r
rwa(df, outcome, predictors, applysigns = FALSE, plot = TRUE)
```

**Arguments**

- `df` Data frame or tibble to be passed through.
- `outcome` Outcome variable, to be specified as a string or bare input. Must be a numeric variable.
- `predictors` Predictor variable(s), to be specified as a vector of string(s) or bare input(s). All variables must be numeric.
- `applysigns` Logical value specifying whether to show an estimate that applies the sign. Defaults to `FALSE`.
- `plot` Logical value specifying whether to plot the rescaled importance metrics.

**Details**

`rwa()` produces raw relative weight values (epsilons) as well as rescaled weights (scaled as a percentage of predictable variance) for every predictor in the model. Signs are added to the weights when the `applysigns` argument is set to `TRUE`. See [https://relativeimportance.davidson.edu/multipleregression.html](https://relativeimportance.davidson.edu/multipleregression.html) for the original implementation that inspired this package.

**Value**

`rwa()` returns a list of outputs, as follows:

- `predictors`: character vector of names of the predictor variables used.
- `rsquare`: the rsquare value of the regression model.
- `result`: the final output of the importance metrics.
  - The `Rescaled.RelWeight` column sums up to 100.
  - The `Sign` column indicates whether a predictor is positively or negatively correlated with the outcome.
- `n`: indicates the number of observations used in the analysis.
- `lambda`:
- `RXX`: Correlation matrix of all the predictor variables against each other.
- `RXY`: Correlation values of the predictor variables against the outcome variable.
Examples

library(ggplot2)
 rwa(diamonds,"price",c("depth","carat"))
