Package ‘tidyr’

January 23, 2020

Title Tidy Messy Data

Version 1.0.2

Description Tools to help to create tidy data, where each column is a variable, each row is an observation, and each cell contains a single value. ‘tidyr’ contains tools for changing the shape (pivoting) and hierarchy (nesting and ‘unnesting’) of a dataset, turning deeply nested lists into rectangular data frames (‘rectangling’), and extracting values out of string columns. It also includes tools for working with missing values (both implicit and explicit).

Description

Song rankings for billboard top 100 in the year 2000

Usage

billboard
chop

Format
A dataset with variables:

- **artist**  Artist name
- **track**  Song name,
- **date.enter**  Date the song entered the top 100
- **wk1 – wk76**  Rank of the song in each week after it entered

chop  

**Chop and unchop**

Description
**Maturing**
Chopping and unchopping preserve the width of a data frame, changing its length. `chop()` makes a data frame shorter by converting rows within each group into list-columns. `unchop()` makes a data frame longer by expanding list-columns so that each element of the list-column gets its own row in the output.

Usage
```r
chop(data, cols)
unchop(data, cols, keep_empty = FALSE, ptype = NULL)
```

Arguments
- **data**  A data frame.
- **cols**  Column to chop or unchop (automatically quoted). This should be a list-column containing generalised vectors (e.g. any mix of `NULL`s, atomic vector, S3 vectors, a lists, or data frames).
- **keep_empty**  By default, you get one row of output for each element of the list your unchopping/unnesting. This means that if there's a size-0 element (like `NULL` or an empty data frame), that entire row will be dropped from the output. If you want to preserve all rows, use `keep_empty = TRUE` to replace size-0 elements with a single row of missing values.
- **ptype**  Optionally, supply a data frame prototype for the output `cols`, overriding the default that will be guessed from the combination of individual values.

Details
Generally, unchopping is more useful than chopping because it simplifies a complex data structure, and `nest()`ing is usually more appropriate that `chop()`ing’ since it better preserves the connections between observations.
Examples

```r
# Chop
df <- tibble(x = c(1, 1, 2, 2, 3), y = 1:6, z = 6:1)
# Note that we get one row of output for each unique combination of non-chopped variables
df %>% chop(c(y, z))
# cf nest
df %>% nest(data = c(y, z))

# Unchop
df <- tibble(x = 1:4, y = list(integer(), 1L, 1:2, 1:3))
df %>% unchop(y)
df %>% unchop(y, keep_empty = TRUE)

# Incompatible types
# If the list-col contains types that can not be natively
df <- tibble(x = 1:2, y = list("1", 1:3))
try(df %>% unchop(y))
df %>% unchop(y, ptype = tibble(y = integer()))
df %>% unchop(y, ptype = tibble(y = character()))
df %>% unchop(y, ptype = tibble(y = list()))

# Unchopping data frames
# Unchopping a list-col of data frames must generate a df-col because unchop leaves the column names unchanged
df <- tibble(x = 1:3, y = list(NULL, tibble(x = 1), tibble(y = 1:2)))
df %>% unchop(y)
df %>% unchop(y, keep_empty = TRUE)
```

**complete**

*Complete a data frame with missing combinations of data*

### Description

Turns implicit missing values into explicit missing values. This is a wrapper around `expand()`, `dplyr::left_join()` and `replace_na()` that’s useful for completing missing combinations of data.

### Usage

```r
complete(data, ..., fill = list())
```

### Arguments

- **data**
  - A data frame.
- **...**
  - Specification of columns to expand. Columns can be atomic vectors or lists.

To find all unique combinations of x, y and z, including those not found in the data, supply each variable as a separate argument. To find only the combinations that occur in the data, use `nest: expand(df, nesting(x, y, z))`.

You can combine the two forms. For example, `expand(df, nesting(school_id, student_id), date)` would produce a row for every student for each date.
For factors, the full set of levels (not just those that appear in the data) are used. For continuous variables, you may need to fill in values that don’t appear in the data: to do so use expressions like year = 2010:2020 or year = \link{full_seq}(year,1). Length-zero (empty) elements are automatically dropped.

**fill**

A named list that for each variable supplies a single value to use instead of NA for missing combinations.

**Details**

If you supply fill, these values will also replace existing explicit missing values in the data set.

**Examples**

```r
library(dplyr, warn.conflicts = FALSE)

def <- tibble(
  group = c(1:2, 1),
  item_id = c(1:2, 2),
  item_name = c("a", "b", "b"),
  value1 = 1:3,
  value2 = 4:6
)
def %>% complete(group, nesting(item_id, item_name))

# You can also choose to fill in missing values
def %>% complete(group, nesting(item_id, item_name), fill = list(value1 = 0))
```

---

**construction**

*Completed construction in the US in 2018*

**Description**

Completed construction in the US in 2018

**Usage**

`construction`

**Format**

A dataset with variables:

- **Year,Month** Record date
- 1 unit, 2 to 4 units, 5 units or more Number of completed units of each size
- **Northeast, Midwest, South, West** Number of completed units in each region

**Source**

Completions of "New Residential Construction" found in Table 5 at https://www.census.gov/construction/nrc/xls/newresconst.xls (downloaded March 2019)
Description
Drop rows containing missing values

Usage

drop_na(data, ...)

Arguments

data A data frame.

... A selection of columns. If empty, all variables are selected. You can supply bare variable names, select all variables between x and z with x:z, exclude y with -y. For more options, see the dplyr::select() documentation. See also the section on selection rules below.

Rules for selection
Arguments for selecting columns are passed to tidyselect::vars_select() and are treated specially. Unlike other verbs, selecting functions make a strict distinction between data expressions and context expressions.

- A data expression is either a bare name like x or an expression like x:y or c(x, y). In a data expression, you can only refer to columns from the data frame.
- Everything else is a context expression in which you can only refer to objects that you have defined with <-.

For instance, col1:col3 is a data expression that refers to data columns, while seq(start, end) is a context expression that refers to objects from the contexts.

If you really need to refer to contextual objects from a data expression, you can unquote them with the tidy eval operator !!. This operator evaluates its argument in the context and inlines the result in the surrounding function call. For instance, c(x, !! x) selects the x column within the data frame and the column referred to by the object x defined in the context (which can contain either a column name as string or a column position).

Examples

library(dplyr)
df <- tibble(x = c(1, 2, NA), y = c("a", NA, "b"))
df %>% drop_na()
df %>% drop_na("x")
### expand

**Expand data frame to include all combinations of values**

#### Description

`expand()` is often useful in conjunction with `left_join()` if you want to convert implicit missing values to explicit missing values. Or you can use it in conjunction with `anti_join()` to figure out which combinations are missing.

#### Usage

```r
expand(data, ...)  
crossing(...)  
nesting(...)  
```

#### Arguments

- `data`:
  - A data frame.

- `...`:
  - Specification of columns to expand. Columns can be atomic vectors or lists.
  - To find all unique combinations of `x`, `y` and `z`, including those not found in the data, supply each variable as a separate argument. To find only the combinations that occur in the data, use `nest`: `expand(df, nesting(x, y, z))`.
  - You can combine the two forms. For example, `expand(df, nesting(school_id, student_id), date)` would produce a row for every student for each date.
  - For factors, the full set of levels (not just those that appear in the data) are used.
  - For continuous variables, you may need to fill in values that don’t appear in the data: to do so use expressions like `year = \link{full_seq}(year,1)`.
  - Length-zero (empty) elements are automatically dropped.

#### Details

`crossing()` is a wrapper around `expand_grid()` that deduplicates and sorts each input. `nesting()` is the complement to `crossing()`: it only keeps combinations of values that appear in the data.

#### See Also

- `complete()` for a common application of `expand`: completing a data frame with missing combinations. `expand_grid()` is low-level that doesn’t deduplicate or sort values.

#### Examples

```r
library(dplyr)  
# All possible combinations of vs & cyl, even those that aren't  
# present in the data  
expand(mtcars, vs, cyl)  

# Only combinations of vs and cyl that appear in the data  
expand(mtcars, nesting(vs, cyl))  
```
# Implicit missings

df <- tibble(
    qtr = c(1, 2, 3, 4, 1, 2, 3),
    return = rnorm(7)
)
df %>% expand(year, qtr)
df %>% expand(year = 2010:2012, qtr)
df %>% expand(year = full_seq(year, 1), qtr)
df %>% complete(year = full_seq(year, 1), qtr)

# Nesting

# Each person was given one of two treatments, repeated three times
# But some of the replications haven't happened yet, so we have incomplete data:
experiment <- tibble(
    name = rep(c("Alex", "Robert", "Sam"), c(3, 2, 1)),
    trt = rep(c("a", "b", "a"), c(3, 2, 1)),
    rep = c(1, 2, 3, 1, 2, 1),
    measurement_1 = runif(6),
    measurement_2 = runif(6)
)

# We can figure out the complete set of data with expand()
# Each person only gets one treatment, so we nest name and trt together:
all <- experiment %>% expand(nesting(name, trt), rep)
all

# We can use anti_join to figure out which observations are missing
all %>% anti_join(experiment)

# And use right_join to add in the appropriate missing values to the original data
experiment %>% right_join(all)
# Or use the complete() short-hand
experiment %>% complete(nesting(name, trt), rep)

# Generate all combinations with expand():
formulas <- list(
    formula1 = Sepal.Length - Sepal.Width,
    formula2 = Sepal.Length - Sepal.Width + Petal.Width,
    formula3 = Sepal.Length - Sepal.Width + Petal.Width + Petal.Length
)
data <- split(iris, iris$Species)
crossing(formula = formulas, data)

---

**expand_grid**

Create a tibble from all combinations of inputs

**Description**

Create a tibble from all combinations of inputs

**Usage**

expand_grid(...)
Arguments

Name-value pairs. The name will become the column name in the output.

Value

A tibble with one column for each input in . . . The output will have one row for each combination of the inputs, i.e. the size be equal to the product of the sizes of the inputs. This implies that if any input has length 0, the output will have zero rows.

Compared to expand.grid

- Varies the first element fastest.
- Never converts strings to factors.
- Does not add any additional attributes.
- Returns a tibble, not a data frame.
- Can expand any generalised vector, including data frames.

Examples

```r
expand_grid(x = 1:3, y = 1:2)
expand_grid(l1 = letters, l2 = LETTERS)

# Can also expand data frames
expand_grid(df = data.frame(x = 1:2, y = c(2, 1)), z = 1:3)
# And matrices
expand_grid(x1 = matrix(1:4, nrow = 2), x2 = matrix(5:8, nrow = 2))
```

---

**extract**

*Extract a character column into multiple columns using regular expression groups*

**Description**

Given a regular expression with capturing groups, `extract()` turns each group into a new column. If the groups don’t match, or the input is NA, the output will be NA.

**Usage**

```r
extract(
  data,
  col,
  into,
  regex = "([[:alnum:]])",
  remove = TRUE,
  convert = FALSE,
  ...
)
```
Arguments

- **data**: A data frame.
- **col**: Column name or position. This is passed to `tidyselect::vars_pull()`. This argument is passed by expression and supports quasiquotation (you can unquote column names or column positions).
- **into**: Names of new variables to create as character vector. Use `NA` to omit the variable in the output.
- **regex**: A regular expression used to extract the desired values. There should be one group (defined by ()) for each element of `into`.
- **remove**: If `TRUE`, remove input column from output data frame.
- **convert**: If `TRUE`, will run `type.convert()` with `as.is = TRUE` on new columns. This is useful if the component columns are integer, numeric or logical. NB: this will cause string “NA”s to be converted to `NA`s.
- **...**: Additional arguments passed on to methods.

See Also

- `separate()` to split up by a separator.

Examples

```r
df <- data.frame(x = c(NA, "a-b", "a-d", "b-c", "d-e"))
df %>% extract(x, "A")
df %>% extract(x, c("A", "B"), "([[:alnum:]]+)-([[:alnum:]]+)")

# If no match, NA:
df %>% extract(x, c("A", "B"), "([a-d]+)-([a-d]+)"
```

---

**fill**

*Fill in missing values with previous or next value*

**Description**

Fills missing values in selected columns using the next or previous entry. This is useful in the common output format where values are not repeated, and are only recorded when they change.

**Usage**

```r
fill(data, ..., .direction = c("down", "up", "downup", "updown"))
```

**Arguments**

- **data**: A data frame.
- **...**: A selection of columns. If empty, nothing happens. You can supply bare variable names, select all variables between `x` and `z` with `x:z`, exclude `y` with `~y`. For more selection options, see the `dplyr::select()` documentation.
- **.direction**: Direction in which to fill missing values. Currently either "down" (the default), "up", "downup" (i.e. first down and then up) or "updown" (first up and then down).
Details
Missing values are replaced in atomic vectors; NULLs are replaced in lists.

Examples

df <- data.frame(Month = 1:12, Year = c(2000, rep(NA, 11)))
df %>% fill(Year)

Description
Information about fish swimming down a river: each station represents an autonomous monitor that records if a tagged fish was seen at that location. Fish travel in one direction (migrating downstream). Information about misses is just as important as hits, but is not directly recorded in this form of the data.

Usage
fish_encounters

Format
A dataset with variables:

- fish  Fish identifier
- station Measurement station
- seen  Was the fish seen? (1 if yes, and true for all rows)

Source
Dataset provided by Myfanwy Johnston; more details at https://fishsciences.github.io/post/visualizing-fish-encounter-histories/

full_seq
Create the full sequence of values in a vector

Description
This is useful if you want to fill in missing values that should have been observed but weren’t. For example, full_seq(c(1,2,4,6),1) will return 1:6.

Usage
full_seq(x, period, tol = 1e-06)
Arguments

- **x**: A numeric vector.
- **period**: Gap between each observation. The existing data will be checked to ensure that it is actually of this periodicity.
- **tol**: Numerical tolerance for checking periodicity.

Examples

```r
full_seq(c(1, 2, 4, 5, 10), 1)
```

Description

**Retired**

Development on `gather()` is complete, and for new code we recommend switching to `pivot_longer()`, which is easier to use, more featureful, and still under active development. `df %>% gather("key", "value", x, y, z)` is equivalent to `df %>% pivot_longer(c(x, y, z), names_to = "key", values_to = "value")`

See more details in vignette("pivot").

Usage

```r
gather(
  data,
  key = "key",
  value = "value",
  ..., 
  na.rm = FALSE,
  convert = FALSE,
  factor_key = FALSE
)
```

Arguments

- **data**: A data frame.
- **key, value**: Names of new key and value columns, as strings or symbols. This argument is passed by expression and supports quasiquotation (you can unquote strings and symbols). The name is captured from the expression with `rlang::ensym()` (note that this kind of interface where symbols do not represent actual objects is now discouraged in the tidyverse; we support it here for backward compatibility).
- **...**: A selection of columns. If empty, all variables are selected. You can supply bare variable names, select all variables between `x` and `z` with `x:z`, exclude `y` with `~y`. For more options, see the `dplyr::select()` documentation. See also the section on selection rules below.
- **na.rm**: If `TRUE`, will remove rows from output where the value column is `NA`.
- **convert**: If `TRUE` will automatically run `type.convert()` on the key column. This is useful if the column types are actually numeric, integer, or logical.
- **factor_key**: If `FALSE`, the default, the key values will be stored as a character vector. If `TRUE`, will be stored as a factor, which preserves the original ordering of the columns.
Rules for selection

Arguments for selecting columns are passed to `tidyselect::vars_select()` and are treated specially. Unlike other verbs, selecting functions make a strict distinction between data expressions and context expressions.

- A data expression is either a bare name like `x` or an expression like `x:y` or `c(x,y)`. In a data expression, you can only refer to columns from the data frame.
- Everything else is a context expression in which you can only refer to objects that you have defined with `<-`.

For instance, `col1:col3` is a data expression that refers to data columns, while `seq(start, end)` is a context expression that refers to objects from the contexts.

If you really need to refer to contextual objects from a data expression, you can unquote them with the tidy eval operator `!!`. This operator evaluates its argument in the context and inlines the result in the surrounding function call. For instance, `c(x, !!x)` selects the `x` column within the data frame and the column referred to by the object `x` defined in the context (which can contain either a column name as string or a column position).

Examples

```r
library(dplyr)
# From https://stackoverflow.com/questions/1181060
stocks <- tibble(
  time = as.Date('2009-01-01') + 0:9,
  X = rnorm(10, 0, 1),
  Y = rnorm(10, 0, 2),
  Z = rnorm(10, 0, 4)
)

gather(stocks, "stock", "price", -time)
stocks %>% gather("stock", "price", -time)

# get first observation for each Species in iris data -- base R
mini_iris <- iris[c(1, 51, 101), ]
# gather Sepal.Length, Sepal.Width, Petal.Length, Petal.Width
gather(mini_iris, key = "flower_att", value = "measurement",
  Sepal.Length, Sepal.Width, Petal.Length, Petal.Width)
# same result but less verbose
gather(mini_iris, key = "flower_att", value = "measurement", -Species)

# repeat iris example using dplyr and the pipe operator
library(dplyr)
mini_iris <-
iris %>%
group_by(Species) %>%
slice(1)
mini_iris %>% gather(key = "flower_att", value = "measurement", -Species)
```

hoist

Rectangle a nested list into a tidy tibble
Description

Maturing

hoist(), unnest_longer(), and unnest_wider() provide tools for rectangling, collapsing deeply nested lists into regular columns. hoist() allows you to selectively pull components of a list-column out into their own top-level columns, using the same syntax as purrr::pluck(). unnest_wider() turns each element of a list-column into a column, and unnest_longer() turns each element of a list-column into a row. unnest_auto() picks between unnest_wider() or unnest_longer() based heuristics described below.

Learn more in vignette("rectangle").

Usage

hoist(.data, .col, ..., .remove = TRUE, .simplify = TRUE, .ptype = list())

unnest_longer(
  data,
  col,
  values_to = NULL,
  indices_to = NULL,
  indices_include = NULL,
  names_repair = "check_unique",
  simplify = TRUE,
  ptype = list()
)

unnest_wider(
  data,
  col,
  names_sep = NULL,
  simplify = TRUE,
  names_repair = "check_unique",
  ptype = list()
)

unnest_auto(data, col)

Arguments

.data, data A data frame.
.col, col List-column to extract components from.
... Components of .col to turn into columns in the form col_name = "pluck_specification". You can pluck by name with a character vector, by position with an integer vector, or with a combination of the two with a list. See purrr::pluck() for details.
.remove If TRUE, the default, will remove extracted components from .col. This ensures that each value lives only in one place.
.simplify If TRUE, will attempt to simplify lists of length-1 vectors to an atomic vector
.ptype Optionally, a named list of prototypes declaring the desired output type of each component.
.values_to Name of column to store vector values. Defaults to col.
indices_to  A string giving the name of column which will contain the inner names or position (if not named) of the values. Defaults to col with _id suffix

indices_include  Add an index column? Defaults to TRUE when col has inner names.

names_repair  Used to check that output data frame has valid names. Must be one of the following options:
   • "minimal": no name repair or checks, beyond basic existence,
   • "unique": make sure names are unique and not empty,
   • "check_unique": (the default), no name repair, but check they are unique,
   • "universal": make the names unique and syntactic
   • a function: apply custom name repair.
   • tidyr_legacy: use the name repair from tidyr 0.8.
   • a formula: a purrr-style anonymous function (see rlang::as_function())

See vctrs::vec_as_names() for more details on these terms and the strategies used to enforce them.

simplify  If TRUE, will attempt to simplify lists of length-1 vectors to an atomic vector

ptype  Optionally, supply a data frame prototype for the output cols, overriding the default that will be guessed from the combination of individual values.

names_sep  If NULL, the default, the names of new columns will come directly from the inner data frame.
   If a string, the names of the new columns will be formed by pasting together the outer column name with the inner names, separated by names_sep.

Unnest variants

The three unnest() functions differ in how they change the shape of the output data frame:

   • unnest_wider() preserves the rows, but changes the columns.
   • unnest_longer() preserves the columns, but changes the rows
   • unnest() can change both rows and columns.

These principles guide their behaviour when they are called with a non-primary data type. For example, if you unnest_wider() a list of data frames, the number of rows must be preserved, so each column is turned into a list column of length one. Or if you unnest_longer() a list of data frame, the number of columns must be preserved so it creates a packed column. I’m not sure how if these behaviours are useful in practice, but they are theoretically pleasing.

unnest_auto() heuristics

unnest_auto() inspects the inner names of the list-col:

   • If all elements are unnamed, it uses unnest_longer()
   • If all elements are named, and there’s at least one name in common across all components, it uses unnest_wider()
   • Otherwise, it falls back to unnest_longer(indices_include = TRUE).
Examples

```r
df <- tibble(
  character = c("Toothless", "Dory"),
  metadata = list(
    list(
      species = "dragon",
      color = "black",
      films = c(
        "How to Train Your Dragon",
        "How to Train Your Dragon 2",
        "How to Train Your Dragon: The Hidden World"
      )
    ),
    list(
      species = "clownfish",
      color = "blue",
      films = c("Finding Nemo", "Finding Dory")
    )
  )
)

df

# Turn all components of metadata into columns
df %>% unnest_wider(metadata)

# Extract only specified components
df %>% hoist(metadata,
  species = "species",
  first_film = list("films", 1L),
  third_film = list("films", 3L)
)

df %>%
  unnest_wider(metadata) %>%
  unnest_longer(films)

# unnest_longer() is useful when each component of the list should
# form a row

df <- tibble(
  x = 1:3,
  y = list(NULL, 1:3, 1:5)
)

df %>% unnest_longer(y)

# Automatically creates names if widening

df %>% unnest_wider(y)

# And similarly if the vectors are named
df <- tibble(
  x = 1:2,
  y = list(c(a = 1, b = 2), c(a = 10, b = 11, c = 12))
)

df %>% unnest_wider(y)
df %>% unnest_longer(y)
```
**Nest and unnest**

**Description**

Nesting creates a list-column of data frames; unnesting flattens it back out into regular columns. Nesting is implicitly a summarising operation: you get one row for each group defined by the non-nested columns. This is useful in conjunction with other summaries that work with whole datasets, most notably models.

Learn more in `vignette("nest")`.

**Usage**

```
nest(.data, ..., .key = deprecated())
```

```
unnest(
  data, 
  cols, 
  ..., 
  keep_empty = FALSE, 
  ptype = NULL, 
  names_sep = NULL, 
  names_repair = "check_unique", 
  .drop = deprecated(), 
  .id = deprecated(), 
  .sep = deprecated(), 
  .preserve = deprecated()
)
```

**Arguments**

- `.data`: A data frame.
- `...`: Name-variable pairs of the form `new_col = c(col1, col2, col3)`, that describe how you wish to nest existing columns into new columns. The right hand side can be any expression supported by tidyselect. **Deprecated**: previously you could write `df %>% nest(x, y, z) and df %>% unnest(x, y, z)`. Convert to `df %>% nest(data = c(x, y, z)) and df %>% unnest(c(x, y, z))`. If you previously created new variable in `unnest()` you’ll now need to do it explicitly with `mutate()`. Convert `df %>% unnest(y = fun(x, y, z))` to `df %>% mutate(y = fun(x, y, z)) %>% unnest(y)`.
- `.key`: **Deprecated**: No longer needed because of the new `new_col = c(col1, col2, col3)` syntax.
- `data`: A data frame.
- `cols`: Names of columns to unnest.
- `keep_empty`: By default, you get one row of output for each element of the list your unchopping/unnesting. This means that if there’s a size-0 element (like NULL or an empty data frame), that entire row will be dropped from the output. If you want
to preserve all rows, use `keep_empty = TRUE` to replace size-0 elements with a single row of missing values.

**ptype**
Optionally, supply a data frame prototype for the output `cols`, overriding the default that will be guessed from the combination of individual values.

**names_sep**
If `NULL`, the default, the names of new columns will come directly from the inner data frame.
If a string, the names of the new columns will be formed by pasting together the outer column name with the inner names, separated by `names_sep`.

**names_repair**
Used to check that output data frame has valid names. Must be one of the following options:
- "minimal": no name repair or checks, beyond basic existence,
- "unique": make sure names are unique and not empty,
- "check_unique": (the default), no name repair, but check they are unique,
- "universal": make the names unique and syntactic
- a function: apply custom name repair.
- `tidyr_legacy`: use the name repair from tidyr 0.8.
- a formula: a purrr-style anonymous function (see `rlang::as_function()`)
See `vctrs::vec_as_names()` for more details on these terms and the strategies used to enforce them.

**.drop, .preserve**
**Deprecated**: all list-columns are now preserved; If there are any that you don’t want in the output use `select()` to remove them prior to unnesting.

**.id**
**Deprecated**: convert `df %>% unnest(x, .id = "id")` to `df %>% mutate(id = names(x)) %>% unnest()`

**.sep**
**Deprecated**: use `names_sep` instead.

**New syntax**
tidyr 1.0.0 introduced a new syntax for `nest()` and `unnest()` that’s designed to be more similar to other functions. Converting to the new syntax should be straightforward (guided by the message you’ll receive) but if you just need to run an old analysis, you can easily revert to the previous behaviour using `nest_legacy()` and `unnest_legacy()` as follows:

```r
library(tidyr)
nest <- nest_legacy
unnest <- unnest_legacy
```

**Grouped data frames**

`df %>% nest(x, y)` specifies the columns to be nested; i.e. the columns that will appear in the inner data frame. Alternatively, you can `nest()` a grouped data frame created by `dplyr::group_by()`.
The grouping variables remain in the outer data frame and the others are nested. The result preserves the grouping of the input.

Variables supplied to `nest()` will override grouping variables so that `df %>% group_by(x, y) %>% nest(z)` will be equivalent to `df %>% nest(z)`.

**Examples**

```r
df <- tibble(x = c(1, 1, 1, 2, 2, 3), y = 1:6, z = 6:1)
# Note that we get one row of output for each unique combination of
# non-nested variables
```
df %>% nest(data = c(y, z))  # chop does something similar, but retains individual columns
df %>% chop(c(y, z))

# use tidyselect syntax and helpers, just like in dplyr::select()
df %>% nest(data = one_of("y", "z"))

iris %>% nest(data = ~Species)
nest_vars <- names(iris)[1:4]
iris %>% nest(data = one_of(nest_vars))
iris %>%
  nest(petal = starts_with("Petal"), sepal = starts_with("Sepal"))
iris %>%
  nest(width = contains("Width"), length = contains("Length"))

# Nesting a grouped data frame nests all variables apart from the group vars
library(dplyr)
fish_encounters %>%
  group_by(fish) %>%
  nest()

# Nesting is often useful for creating per group models
mtcars %>%
  group_by(cyl) %>%
  nest() %>%
  mutate(models = lapply(data, function(df) lm(mpg ~ wt, data = df)))

# unnest() is primarily designed to work with lists of data frames
df <- tibble(
  x = 1:3,
  y = list(
    NULL,
    tibble(a = 1, b = 2),
    tibble(a = 1:3, b = 3:1)
  )
)
df %>% unnest(y)
df %>% unnest(y, keep_empty = TRUE)

# If you have lists of lists, or lists of atomic vectors, instead
# see hoist(), unnest_wider(), and unnest_longer()

# # You can unnest multiple columns simultaneously
df <- tibble(
  a = list(c("a", "b", "c"),
           list(1:2, 3),
           c(11, 22)),
  b = list(1:2, 3)
)
df %>% unnest(c(a, b))

# Compare with unnesting one column at a time, which generates
# the Cartesian product
df %>% unnest(a) %>% unnest(b)

nest_legacy  Legacy versions of nest() and unnest()
Description

Retired
tidyR 1.0.0 introduced a new syntax for `nest()` and `unnest()`. The majority of existing usage should be automatically translated to the new syntax with a warning. However, if you need to quickly roll back to the previous behaviour, these functions provide the previous interface. To make old code work as is, add the following code to the top of your script:

```r
library(tidyR)
nest <- nest_legacy
unnest <- unnest_legacy
```

Usage

```r
nest_legacy(data, ..., .key = "data")
unnest_legacy(data, ..., .drop = NA, .id = NULL, .sep = NULL, .preserve = NULL)
```

Arguments

data  A data frame.

... Specification of columns to unnest. Use bare variable names or functions of variables. If omitted, defaults to all list-cols.

.key The name of the new column, as a string or symbol. This argument is passed by expression and supports quasiquotation (you can unquote strings and symbols). The name is captured from the expression with `rlang::ensym()` (note that this kind of interface where symbols do not represent actual objects is now discouraged in the tidyverse; we support it here for backward compatibility).

.drop Should additional list columns be dropped? By default, `unnest()` will drop them if unnesting the specified columns requires the rows to be duplicated.

.id Data frame identifier - if supplied, will create a new column with name .id, giving a unique identifier. This is most useful if the list column is named.

.sep If non-NULL, the names of unnested data frame columns will combine the name of the original list-col with the names from the nested data frame, separated by .sep.

.preserve Optionally, list-columns to preserve in the output. These will be duplicated in the same way as atomic vectors. This has `dplyr::select()` semantics so you can preserve multiple variables with .preserve = c(x,y) or .preserve = starts_with("list").

Examples

```r
# Nest and unnest are inverses
df <- data.frame(x = c(1, 1, 2), y = 3:1)
df %>% nest_legacy(y)
df %>% nest_legacy(y) %>% unnest_legacy()

# nesting -----------------------------------------------
as_tibble(iris) %>% nest_legacy(~Species)
as_tibble(chickwts) %>% nest_legacy(weight)

# unnesting -----------------------------------------------
df <- tibble(
  x = 1:2,
  y = list(  
    tibble(z = 1),  
    tibble(z = 3:4)  
  )
)
df %>% unnest_legacy(y)

# You can also unnest multiple columns simultaneously
df <- tibble(
  a = list(c("a", "b"), "c"),
  b = list(1:2, 3),
  c = c(11, 22)
)
df %>% unnest_legacy(a, b)
# If you omit the column names, it'll unnest all list-cols
df %>% unnest_legacy()

pack  

Pack and unpack

Description

Maturing

Packing and unpacking preserve the length of a data frame, changing its width. pack() makes df narrow by collapsing a set of columns into a single df-column. unpack() makes data wider by expanding df-columns back out into individual columns.

Usage

pack(data, ...)

unpack(data, cols, names_sep = NULL, names_repair = "check_unique")

Arguments

data  

A data frame.

...  

Name-variable pairs of the form new_col = c(col1, col2, col3), that describe how you wish to pack existing columns into new columns. The right hand side can be any expression supported by tidyselect.

cols  

Name of column that you wish to unpack.

names_sep  

If NULL, the default, the names of new columns will come directly from the inner data frame.

If a string, the names of the new columns will be formed by pasting together the outer column name with the inner names, separated by names_sep.

names_repair  

Used to check that output data frame has valid names. Must be one of the following options:

• "minimal": no name repair or checks, beyond basic existence,
• "unique": make sure names are unique and not empty,
pivot_longer

Description

Maturing

pivot_longer() "lengthens" data, increasing the number of rows and decreasing the number of columns. The inverse transformation is pivot_wider().

Learn more in vignette("pivot").

Usage

pivot_longer(
data,
cols,
names_to = "name",
)

- "check_unique": (the default), no name repair, but check they are unique,
- "universal": make the names unique and syntactic
- a function: apply custom name repair.
- tidyr_legacy: use the name repair from tidyr 0.8.
- a formula: a purrr-style anonymous function (see rlang::as_function())

See vctrs::vec_as_names() for more details on these terms and the strategies used to enforce them.

Details

Generally, unpacking is more useful than packing because it simplifies a complex data structure. Currently, few functions work with df-cols, and they are mostly a curiosity, but seem worth exploring further because they mimic the nested column headers that are so popular in Excel.

Examples

# Packing
# It's not currently clear why you would ever want to pack columns
# since few functions work with this sort of data.
df <- tibble(x1 = 1:3, x2 = 4:6, x3 = 7:9, y = 1:3)
df
df %>% pack(x = starts_with("x"))
df %>% pack(x = c(x1, x2, x3), y = y)

# Unpacking

df <- tibble(
  x = 1:3,
  y = tibble(a = 1:3, b = 3:1),
  z = tibble(X = c("a", "b", "c"), Y = runif(3), Z = c(TRUE, FALSE, NA))
)
df
df %>% unpack(y)
df %>% unpack(c(y, z))
df %>% unpack(c(y, z), names_sep = ".")
pivot_longer

```r
names_prefix = NULL,
names_sep = NULL,
names_pattern = NULL,
names_ptypes = list(),
names_repair = "check_unique",
values_to = "value",
values_drop_na = FALSE,
values_ptypes = list()
```

Arguments

data
- A data frame to pivot.

cols
- Columns to pivot into longer format. This takes a tidyselect specification.

names_to
- A string specifying the name of the column to create from the data stored in the column names of data.
  - Can be a character vector, creating multiple columns, if names_sep or names_pattern is provided.

names_prefix
- A regular expression used to remove matching text from the start of each variable name.

names_sep, names_pattern
- If names_to contains multiple values, these arguments control how the column name is broken up.
  - names_sep takes the same specification as separate(), and can either be a numeric vector (specifying positions to break on), or a single string (specifying a regular expression to split on).
  - names_pattern takes the same specification as extract(), a regular expression containing matching groups (()).
  - If these arguments does not give you enough control, use pivot_longer_spec() to create a spec object and process manually as needed.

names_ptypes, values_ptypes
- A list of of column name-prototype pairs. A prototype (or ptype for short) is a zero-length vector (like integer() or numeric()) that defines the type, class, and attributes of a vector.
  - If not specified, the type of the columns generated from names_to will be character, and the type of the variables generated from values_to will be the common type of the input columns used to generate them.

names_repair
- What happen if the output has invalid column names? The default, "check_unique" is to error if the columns are duplicated. Use "minimal" to allow duplicates in the output, or "unique" to de-duplicated by adding numeric suffixes. See vctrs::vec_as_names() for more options.

values_to
- A string specifying the name of the column to create from the data stored in cell values. If names_to is a character containing the special .value sentinel, this value will be ignored, and the name of the value column will be derived from part of the existing column names.

values_drop_na
- If TRUE, will drop rows that contain only NAs in the value_to column. This effectively converts explicit missing values to implicit missing values, and should generally be used only when missing values in data were created by its structure.
Details

pivot_longer() is an updated approach to gather(), designed to be both simpler to use and to handle more use cases. We recommend you use pivot_longer() for new code; gather() isn’t going away but is no longer under active development.

Examples

# See vignette("pivot") for examples and explanation

# Simplest case where column names are character data
relig_income
relig_income %>%
  pivot_longer(~religion, names_to = "income", values_to = "count")

# Slightly more complex case where columns have common prefix, # and missing missings are structural so should be dropped.
billboard
billboard %>%
pivot_longer(
  cols = starts_with("wk"),
  names_to = "week",
  names_prefix = "wk",
  values_to = "rank",
  values_drop_na = TRUE
)

# Multiple variables stored in column names
who %>% pivot_longer(
  cols = new_sp_m014:newrel_f65,
  names_to = c("diagnosis", "gender", "age"),
  names_pattern = "new_.?(.*)_(.*)",
  values_to = "count"
)

# Multiple observations per row
anscombe
anscombe %>%
pivot_longer(everything()),
  names_to = c(".value", "set"),
  names_pattern = "\.(\.)"

---

pivot_wider

Pivot data from long to wide

Description

Maturing

pivot_wider() "widens" data, increasing the number of columns and decreasing the number of rows. The inverse transformation is pivot_longer().

Learn more in vignette("pivot").
pivot_wider

Usage

pivot_wider(
  data,
  id_cols = NULL,
  names_from = name,
  names_prefix = "",
  names_sep = "_",
  names_repair = "check_unique",
  values_from = value,
  values_fill = NULL,
  values_fn = NULL
)

Arguments

data A data frame to pivot.
id_cols A set of columns that uniquely identifies each observation. Defaults to all
  columns in data except for the columns specified in names_from and values_from.
  Typically used when you have additional variables that is directly related.

names_from, values_from
  A pair of arguments describing which column (or columns) to get the name of
  the output column (name_from), and which column (or columns) to get the cell
  values from (values_from).
  If values_from contains multiple values, the value will be added to the front of
  the output column.

names_prefix String added to the start of every variable name. This is particularly useful
  if names_from is a numeric vector and you want to create syntactic variable
  names.

names_sep If names_from or values_from contains multiple variables, this will be used to
  join their values together into a single string to use as a column name.

names_repair What happen if the output has invalid column names? The default, "check_unique"
  is to error if the columns are duplicated. Use "minimal" to allow duplicates
  in the output, or "unique" to de-duplicated by adding numeric suffixes. See
  vctrs::vec_as_names() for more options.

values_fill Optionally, a named list specifying what each value should be filled in with
  when missing.

values_fn Optionally, a named list providing a function that will be applied to the value
  in each cell in the output. You will typically use this when the combination of
  id_cols and value column does not uniquely identify an observation.

Details

pivot_wider() is an updated approach to spread(), designed to be both simpler to use and to
handle more use cases. We recomend you use pivot_wider() for new code; spread() isn't going
away but is no longer under active development.

See Also

pivot_wider_spec() to pivot "by hand" with a data frame that defines a pivoting specification.
Examples

# See vignette("pivot") for examples and explanation

fish_encounters
fish_encounters %>%
pivot_wider(names_from = station, values_from = seen)

# Fill in missing values
fish_encounters %>%
pivot_wider(
  names_from = station,
  values_from = seen,
  values_fill = list(seen = 0)
)

# Generate column names from multiple variables
us_rent_income %>%
pivot_wider(names_from = variable, values_from = c(estimate, moe))

# Can perform aggregation with values_fn
warpbreaks <- as_tibble(warpbreaks[c("wool", "tension", "breaks")])
warpbreaks
warpbreaks %>%
pivot_wider(
  names_from = wool,
  values_from = breaks,
  values_fn = list(breaks = mean)
)

relig_income

Description

Pew religion and income survey

Usage

relig_income

Format

A dataset with variables:

religion Name of religion
<$10k-Don't know/refused Number of respondents with income range in column name

Source

Downloaded from https://www.pewforum.org/religious-landscape-study/ (downloaded November 2009)
**replace_na**

*Replace missing values*

**Description**

Replace missing values

**Usage**

```r
replace_na(data, replace, ...)
```

**Arguments**

```r
data  A data frame or vector.
replace If `data` is a data frame, a named list giving the value to replace `NA` with for each column. If `data` is a vector, a single value used for replacement.
...

Additional arguments for methods. Currently unused.
```

**Value**

If `data` is a data frame, returns a data frame. If `data` is a vector, returns a vector of class determined by the union of `data` and `replace`.

**See Also**

- `na_if` to replace specified values with a `NA`
- `coalesce` to replace missing values with a specified value
- `recode` to more generally replace values

**Examples**

```r
library(dplyr)
df <- tibble(x = c(1, 2, NA), y = c("a", NA, "b"), z = list(1:5, NULL, 10:20))
df %>% replace_na(list(x = 0, y = "unknown"))
df %>% mutate(x = replace_na(x, 0))

# NULL are the list-col equivalent of NAs
df %>% replace_na(list(z = list(5)))

df$x %>% replace_na(0)
df$y %>% replace_na("unknown")
```
**separate**

Separate a character column into multiple columns using a regular expression separator

**Description**

Given either regular expression or a vector of character positions, `separate()` turns a single character column into multiple columns.

**Usage**

```r
separate(
  data,  
  col,      
  into,    
  sep = "[^[:alnum:]]+",  
  remove = TRUE,  
  convert = FALSE,  
  extra = "warn",  
  fill = "warn",  
  ...       
)
```

**Arguments**

- **data** A data frame.
- **col** Column name or position. This is passed to `tidyselect::vars_pull()`. This argument is passed by expression and supports **quasiquotation** (you can unquote column names or column positions).
- **into** Names of new variables to create as character vector. Use `NA` to omit the variable in the output.
- **sep** Separator between columns. If character, is interpreted as a regular expression. The default value is a regular expression that matches any sequence of non-alphanumeric values. If numeric, interpreted as positions to split at. Positive values start at 1 at the far-left of the string; negative value start at -1 at the far-right of the string. The length of `sep` should be one less than `into`.
- **remove** If `true`, remove input column from output data frame.
- **convert** If `TRUE`, will run `type.convert()` with `as.is = TRUE` on new columns. This is useful if the component columns are integer, numeric or logical. NB: this will cause string "NA"s to be converted to NAs.
- **extra** If `sep` is a character vector, this controls what happens when there are too many pieces. There are three valid options:
  - "warn" (the default): emit a warning and drop extra values.
  - "drop": drop any extra values without a warning.
  - "merge": only splits at most `length(into)` times
- **fill** If `sep` is a character vector, this controls what happens when there are not enough pieces. There are three valid options:
separate_rows

Separate a collapsed column into multiple rows

Description

If a variable contains observations with multiple delimited values, this separates the values and places each one in its own row.

- "warn" (the default): emit a warning and fill from the right
- "right": fill with missing values on the right
- "left": fill with missing values on the left

Additional arguments passed on to methods.

See Also

unite(), the complement, extract() which uses regular expression capturing groups.

Examples

library(dplyr)
df <- data.frame(x = c(NA, "a.b", "a.d", "b.c"))
df %>% separate(x, c("A", "B"))

# If you just want the second variable:
df %>% separate(x, c(NA, "B"))

# If every row doesn't split into the same number of pieces, use
# the extra and fill arguments to control what happens
df <- data.frame(x = c("a", "a b", "a b c", NA))
df %>% separate(x, c("a", "b"))
# The same behaviour drops the c but no warnings
df %>% separate(x, c("a", "b"), extra = "drop", fill = "right")
# Another option:
df %>% separate(x, c("a", "b"), extra = "merge", fill = "left")
# Or you can keep all three
df %>% separate(x, c("a", "b", "c"))

# If only want to split specified number of times use extra = "merge"
df <- data.frame(x = c("x: 123", "y: error: 7"))
df %>% separate(x, c("key", "value"), ": ", extra = "merge")

# Use regular expressions to separate on multiple characters:
df <- data.frame(x = c(NA, "a?b", "a.d", "b:c"))
df %>% separate(x, c("A","B"), sep = "([\d\s\?\:\-\:]\")")

# convert = TRUE detects column classes
df <- data.frame(x = c("a:1", "a:2", "c:4", "d", NA))
df %>% separate(x, c("key","value"), ":") %>% str

df %>% separate(x, c("key","value"), ":", convert = TRUE) %>% str

# Argument col can take quasiquotation to work with strings
var <- "x"
df %>% separate(all.vars, c("key","value"), ":")
Usage

```r
separate_rows(data, ..., sep = "[^[:alnum:]\.]\+", convert = FALSE)
```

Arguments

data  A data frame.
...
A selection of columns. If empty, nothing happens. You can supply bare variable names, select all variables between x and z with x:z, exclude y with ~y. For more selection options, see the `dplyr::select()` documentation.
sep    Separator delimiting collapsed values.
convert If TRUE will automatically run `type.convert()` on the key column. This is useful if the column types are actually numeric, integer, or logical.

Rules for selection

Arguments for selecting columns are passed to `tidyselect::vars_select()` and are treated specially. Unlike other verbs, selecting functions make a strict distinction between data expressions and context expressions.

- A data expression is either a bare name like `x` or an expression like `x:y` or `c(x, y)`. In a data expression, you can only refer to columns from the data frame.
- Everything else is a context expression in which you can only refer to objects that you have defined with `<-`.

For instance, `col1:col3` is a data expression that refers to data columns, while `seq(start, end)` is a context expression that refers to objects from the contexts.

If you really need to refer to contextual objects from a data expression, you can unquote them with the tidy eval operator `!!`. This operator evaluates its argument in the context and inlines the result in the surrounding function call. For instance, `c(x, !! x)` selects the `x` column within the data frame and the column referred to by the object `x` defined in the context (which can contain either a column name as string or a column position).

Examples

```r
df <- data.frame(
  x = 1:3,
  y = c("a", "d,e,f", "g,h"),
  z = c("1", "2,3,4", "5,6"),
  stringsAsFactors = FALSE
)
separate_rows(df, y, z, convert = TRUE)
```

---

**smiths**

Some data about the Smith family

Description

A small demo dataset describing John and Mary Smith.

Usage

smiths
spread

Format
A data frame with 2 rows and 5 columns.

spread

Spread a key-value pair across multiple columns

Description
Retired
Development on spread() is complete, and for new code we recommend switching to pivot_wider(), which is easier to use, more featureful, and still under active development. df %>% spread(key, value) is equivalent to df %>% pivot_wider(names_from = key, values_from = value)
See more details in vignette("pivot").

Usage
spread(data, key, value, fill = NA, convert = FALSE, drop = TRUE, sep = NULL)

Arguments
data
A data frame.

key, value
Column names or positions. This is passed to tidyselect::vars_pull(). These arguments are passed by expression and support quasiquotation (you can unquote column names or column positions).

fill
If set, missing values will be replaced with this value. Note that there are two types of missingness in the input: explicit missing values (i.e. NA), and implicit missings, rows that simply aren’t present. Both types of missing value will be replaced by fill.

convert
If TRUE, type.convert() with asis = TRUE will be run on each of the new columns. This is useful if the value column was a mix of variables that was coerced to a string. If the class of the value column was factor or date, note that will not be true of the new columns that are produced, which are coerced to character before type conversion.

drop
If FALSE, will keep factor levels that don’t appear in the data, filling in missing combinations with fill.

sep
If NULL, the column names will be taken from the values of key variable. If non-NULL, the column names will be given by "<key_name><sep><key_value>".

Examples
library(dplyr)
stocks <- data.frame(
  time = as.Date('2009-01-01') + 0:9,
  X = rnorm(10, 0, 1),
  Y = rnorm(10, 0, 2),
  Z = rnorm(10, 0, 4)
)
stocksm <- stocks %>% gather(stock, price, -time)
stocksm %>% spread(stock, price)
stocksm %>% spread(time, price)

# Spread and gather are complements
df <- data.frame(x = c("a", "b"), y = c(3, 4), z = c(5, 6))
df %>% spread(x, y) %>% gather("x", "y", a:b, na.rm = TRUE)

# Use 'convert = TRUE' to produce variables of mixed type
df <- data.frame(row = rep(c(1, 51), each = 3),
  var = c("Sepal.Length", "Species", "Species_num"),
  value = c(5.1, "setosa", 1, 7.0, "versicolor", 2))
df %>% spread(var, value) %>% str

df %>% spread(var, value, convert = TRUE) %>% str

---

**Description**

Data sets that demonstrate multiple ways to layout the same tabular data.

**Usage**

- table1
- table2
- table3
- table4a
- table4b
- table5

**Format**

An object of class tbl_df (inherits from tbl, data.frame) with 6 rows and 4 columns.

**Details**

The data contains values associated with four variables (country, year, cases, and population), but each table organizes the values in a different layout.

**Source**

uncount

"Uncount" a data frame

Description

Performs the opposite operation to `dplyr::count()`, duplicating rows according to a weighting variable (or expression).

Usage

```
uncount(data, weights, .remove = TRUE, .id = NULL)
```

Arguments

data

A data frame, tibble, or grouped tibble.

weights

A vector of weights. Evaluated in the context of `data`; supports quasiquotation.

.remove

If TRUE, and `weights` is a single

.id

Supply a string to create a new variable which gives a unique identifier for each created row.

Examples

```
df <- tibble(x = c("a", "b"), n = c(1, 2))
uncount(df, n)
uncount(df, n, .id = "id")

# You can also use constants
uncount(df, 2)

# Or expressions
uncount(df, 2 / n)
```

unite

Unite multiple columns into one by pasting strings together

Description

Convenience function to paste together multiple columns into one.

Usage

```
unite(data, col, ..., sep = "_", remove = TRUE, na.rm = FALSE)
```
Arguments

- `data` A data frame.
- `col` The name of the new column, as a string or symbol. This argument is passed by expression and supports quasiquotation (you can unquote strings and symbols). The name is captured from the expression with `rlang::ensym()` (note that this kind of interface where symbols do not represent actual objects is now discouraged in the tidyverse; we support it here for backward compatibility).
- `...` A selection of columns. If empty, all variables are selected. You can supply bare variable names, select all variables between `x` and `z` with `x:z`, exclude `y` with `-y`. For more options, see the `dplyr::select()` documentation. See also the section on selection rules below.
- `sep` Separator to use between values.
- `remove` If `TRUE`, remove input columns from output data frame.
- `na.rm` If `TRUE`, missing values will be remove prior to uniting each value.

Rules for selection

Arguments for selecting columns are passed to `tidyselect::vars_select()` and are treated specially. Unlike other verbs, selecting functions make a strict distinction between data expressions and context expressions.

- A data expression is either a bare name like `x` or an expression like `x:y` or `c(x,y)`. In a data expression, you can only refer to columns from the data frame.
- Everything else is a context expression in which you can only refer to objects that you have defined with `<-`.

For instance, `col1:col3` is a data expression that refers to data columns, while `seq(start,end)` is a context expression that refers to objects from the contexts.

If you really need to refer to contextual objects from a data expression, you can unquote them with `!!`. This operator evaluates its argument in the context and inlines the result in the surrounding function call. For instance, `c(x,!!x)` selects the `x` column within the data frame and the column referred to by the object `x` defined in the context (which can contain either a column name as string or a column position).

See Also

- `separate()`, the complement.

Examples

```r
df <- expand.grid(x = c("a", NA), y = c("b", NA))
df

df %>% unite("z", x:y, remove = FALSE)
# To remove missing values:
df %>% unite("z", x:y, na.rm = TRUE, remove = FALSE)

# Separate is almost the complement of unite
df %>%
    unite("xy", x:y) %>%
    separate(xy, c("x", "y"))
# (but note 'x' and 'y' contain now "NA" not NA)
```
us_rent_income

US rent and income data

Description
Captured from the 2017 American Community Survey using the tidycensus package.

Usage
us_rent_income

Format
A dataset with variables:

GEOID  FIP state identifier
NAME    Name of state
variable Variable name: income = median yearly income, rent = median monthly rent
estimate Estimated value
moe     90% margin of error

who

World Health Organization TB data

Description
A subset of data from the World Health Organization Global Tuberculosis Report, and accompanying global populations.

Usage
who
population

Format
A dataset with the variables
country Country name
iso2, iso3 2 & 3 letter ISO country codes
year Year
new_sp_m014 - new_rel_f65 Counts of new TB cases recorded by group. Column names encode three variables that describe the group (see details).
Details

The data uses the original codes given by the World Health Organization. The column names for columns five through 60 are made by combining new_ to a code for method of diagnosis (rel = relapse, sn = negative pulmonary smear, sp = positive pulmonary smear, ep = extrapulmonary) to a code for gender (f = female, m = male) to a code for age group (014 = 0-14 yrs of age, 1524 = 15-24 years of age, 2534 = 25 to 34 years of age, 3544 = 35 to 44 years of age, 4554 = 45 to 54 years of age, 5564 = 55 to 64 years of age, 65 = 65 years of age or older).

world_bank_pop

Population data from the world bank

Description

Data about population from the World Bank.

Usage

world_bank_pop

Format

A dataset with variables:

- country  Three letter country code
- indicator  Indicator name: SP.POP.GROW = population growth, SP.POP.TOTL = total population, SP.URB.GROW = urban population growth, SP.URB.TOTL = total urban population

2000-2018  Value for each year
